From 1929 to the early 1930s, other researchers were claiming to have demonstrated that the polyunsaturated fatty acids were nutritionally essential. These experiments, like the vitamin E experiments, were done on rats, but the medical establishment was satisfied that rat experiments proved that humans need linoleic or linolenic acid, while they refused to accept that vitamin E was essential for humans. When, in the 1940s, a group of vitamin B_6 researchers showed that the supposed "essential fatty acid deficiency" could be cured by a supplement of vitamin B_6, it became apparent that the polyunsaturated fatty acids slowed metabolism, and reduced all nutritional needs. The thyroid hormone was powerfully suppressed by the "essential" fatty acids.

When we consider the two sets of experiments together, their outstanding feature is the toxicity of the polyunsaturated oils, which in one kind of experiment suppressed metabolism, and in the other kind of experiment created a variety of degenerative conditions.

By the late 1940s and early 1950s, estrogens of various sorts had been synthesized from hydrocarbons, and were being recommended to prevent miscarriages, because "estrogen is the female hormone." The meat industry had found that the polyunsaturated oils were valuable in animal feed, since they suppressed metabolism and made it cheaper to fatten the animals, and these antithyroid oils were next marketed as "heart protective" human foods, though by suppressing the thyroid and destroying vitamin E, they actually contributed to both heart disease and cancer. (Giving estrogen to livestock to improve their feed efficiency, and to people "to prevent heart attacks," was an interesting parallel to the oil promotional campaigns.)

The influence of the food oil industry kept researchers away from the idea that these oils were not safe for food use, and instead tended to support the idea that vitamin E is just an antioxidant, and that the seed oils were the best way to get vitamin E in the diet.

The antifertility effects of the polyunsaturated oils, demonstrated in the vitamin E experiments, weren't at the time understood to have anything to do with estrogen's antifertility effects. But to understand vitamin E, I think we have to consider the close interactions between estrogen and the polyunsatured fatty acids (PUFA). Their actions are closely intertwined, and are antagonized by a variety of energizing and

stabiliizing substances, including saturated fats, progesterone, thyroid, vitamin E, and aspirin.

Generally, chemicals that inhibit enzymes are toxic, producing some sort of symptom or deterioration. But a group of enzymes related to estrogen and PUFA are inhibited by these protective substances. Although under our present diet, these enzymes metabolize the PUFA, in the fetus and newborn they act on our endogenous fats, the series related to the Mead acids. The Mead acid is antiinflammatory, and broadly protective. The dietary PUFA interfere with these natural protective substances,

The enzymes that, if we didn't eat PUFA, would be regulating the Mead series, being activated in response to stress, would be producing antistress substances, which would limit the stress reaction. But as we become increasingly saturated with the anti-vitamin E fats, these enzymes, instead of stopping inflammation, promote it and cause tissue injury. The remaining stress limiting factors, such as progesterone, by correcting the distortions caused by stress, tend to eliminate the conditions which activated the enzymes—in a very indirect form of inhibition.

Many of the events involved in inflammation are increased by estrogen, and decreased by vitamin E. Estrogen causes capillaries to become leaky; vitamin E does the opposite. Estrogen increases platelet aggregation, and decreases a factor that inhibits platelet aggregation; vitamin E does the opposite.

Excess clotting is known to be caused by too much estrogen, and also by a vitamin E deficiency.

Clotting leads to fibrosis, and there is clear evidence that vitamin E prevents and cures fibrotic diseases, but this still isn't generally accepted by the powerful medical institutions. Estrogen and polyunsaturated fats increase fibrosis.

Estrogen increases progstaglandin synthesis, vitamin E decreases their synthesis; estrogen increases the activity of the enzymes COX and LOX, vitamin E decreases their activitiy.[1–3] Estrogen releases enzymes from lysosomes, vitamin E inhibits their release. Beta-glucuronidase, one of these enzymes, can release estrogen at the site of an inflammation.

Estrogen often increases intracellular calcium and protein kinase C, vitamin E has generally opposite effects.

The polyunsaturated fatty acids and their derivatives, the prostaglandins, act as effectors, or amplifiers, of estrogen's actions.

If vitamin E is acting as a protectant against the polyunsaturated fatty acids, that in itself would account for at least some of its antiestrogenic effects.

Besides antagonizing some of the end effects of the toxic fatty acids, vitamin E inhibits lipolysis, lowering the concentration of free fatty acids (the opposite of estrogen's effect), and it also binds to, and inactivates, free fatty acids. The long saturated carbon chain is very important for its full functioning, and this saturated chain might allow it to serve as a substitute for the omega -9 fats, from which the Mead acid is formed. The unsaturated tocotrienols have hardly been tested for the spectrum of true vitamin E activity, and animal studies have suggested that it may be toxic, since it caused liver enlargement.

One possibly crucial protective effect of vitamin E against the polyunsaturated fatty acids that hasn't been explored is the direct destruction of linolenic and linoleic acid. It is known that bacterial vitamin E is involved in the saturation of unsaturated fatty acids, and it is also known that intestinal bacteria turn linoleic and linolenic acids into the fully saturated stearic acid.

> *"No metabolic function is known for alpha-tocopherolquinol or its quinone other than as a cofactor in the biohydrogenation of unsaturated fatty acids that can be carried out by only a few organisms."*[4]

> *"Linoleic acid was significantly decreased ($P < 0.001$) and there was a significant rise ($P < 0.05$) in its hydrogenation product, stearic acid. Linolenic acid was also significantly decreased..." "The study provides evidence that bacteria from the human colon can hydrogenate C_{18} essential polyunsaturated fatty acids."*[5]

Because of the way in which the decision to call vitamin E a simple antioxidant was conditioned by the historical setting, there has been a reluctance, until recently, to give much weight to the pathogenicity of lipid peroxidation and free radicals, partly because lipid peroxidation is only a minor part of the toxicity of the polyunsaturated oils, and there was little support for the investigation of the real nature of their toxicity. This environment has even distorted the actual antioxidant value of the various forms of vitamin E.[6]

The people who say that vitamin E is nothing but an antioxidant sometimes take other antioxidants, with, or instead of, vitamin E. BHT, BHA, and many natural compounds (derived from industrial and agricultural wastes) are often said to be "better than vitamin E" as antioxidants. Anything that can be oxidized and reduced (melatonin, estrogen, tryptophan, carotene, etc.) will function as an antioxidant in some system, but in other circumstances, it can be a pro-oxidant.

The people who think there is benefit in the abstract "antioxidant" function seem to be thinking in terms of something that will, like a ubiquitous fire department, put out every little fire as soon as it starts. I think it's more appropriate to think of the biological antioxidant systems as programs for controlling the arsonists before they can set the fires.

Since the requirement for vitamin E decreases as the consumption of unsaturated fats decreases, the requirement, if any, would be very small if we didn't eat significant quantities of those fats.

In the years since the tocopherols were identified as vitamin E, the material sold for research and for use as a nutritional supplement has changed drastically several times, even when it has been given a specific chemical identity, such as mixed tocopherols or d-alpha tocopherol. Variations in viscosity and color, caused by changes in the impurities, have undoubtedly influenced its biological effects, but the ideology about its antioxidant value has kept researchers from finding out what a particular batch of it really is and what it really does.

> *"We compared the effect of a mixed tocopherol preparation with that of alpha-tocopherol alone on superoxide dismutase (SOD) activity and iNOS expression in cultured myocytes exposed to H-R." "Both tocopherol preparations attenuated cell injury..." "However, mixed-tocopherol preparation was much superior to alpha-tocopherol in terms of myocyte protection..." "Lack of efficacy of commercial tocopherol preparations in clinical trials may reflect absence of gamma- and delta-tocopherols."*[7]

Keeping our diet as free as possible of the polyunsaturated fats, to create something like the "deficiency" state that is so protective (against cancer, trauma, poison, shock, inflammation, infection, etc.) in the animal experiments, seems preferable to trying to saturate ourselves with

antioxidants, considering the imperfectly defined nature of the vitamin E products, and the known toxicity of many of the other antioxidants on the market.

The carcinogenic properties of the polyunsaturated fats have been known for more than 50 years, as has the principle of extending the life span by restricted feeding. More recently several studies have demonstrated that the long lived species contain fewer highly unsaturated fats than the short lived species. Restriction of calories prevents the lipids in the brain, heart, and liver from becoming more unsaturated with aging.[8–11]

When cells are grown in tissue culture without the "essential fatty acids," they become "deficient," and in that state are very resistant to chemical injury, and can be grown indefinitely. Besides being a simple demonstration of the way in which the polyunsaturated fats sensitize cells to injury,[12] these experiments must be an embarrassment to the people who base their argument for the oils' essentiality on a supposed requirement for "making cell membranes." Since the cells can multiply nicely in their deficient state, we have to conclude that the oils aren't needed for "membranes," or maybe that cells resist injury better "without membranes."

In the opposite direction, an excess of insulin or prolactin, or a deficiency of vitamin E, increases the activity of the enzymes that convert linoleic acid into the more highly unsaturated fatty acids. Excess insulin and prolactin are crucially involved in many degenerative diseases.

The highly unsaturated fats suppress respiration in many ways, and these trends toward increased unsaturation with aging, endocrine stress, and vitamin E deficiency parallel the life-long trend toward lower energy production from respiration. Many studies show that vitamin E can protect and improve mitochondrial energy production.[13–17] But the state of so-called essential fatty acid deficiency not only makes mitochondria very resistant to injury, it greatly intensifies their energy production. Vitamin E supplementation is seldom as effective as the absence of the toxic oils.

Many nutrition charts no longer list liver as a good source of vitamin E, but a large portion of an animal's vitamin E is in its liver. This bias in the dietetic literature can be traced to various sources, but a major influence was the campaign in the 1970s by the drug companies that had patented new forms of synthetic "vitamin A." They had physicians and

professors fabricate stories about the great toxicity of natural vitamin A, and placed the stories in national magazines, to clear the field for their supposedly non-toxic products, which have turned out to be disastrously toxic. The result is that many people have fearfully stopped eating liver, because of its vitamin A. The other vitamins in liver, including vitamin K, function very closely with vitamin E, and the stably stored forms of vitamin E are likely to be a good approximation for our needs.

There is still a strong division between what people can say in their professional publications, and what they believe. A man who was influential in designating vitamin E as an antioxidant, M.K. Horwitt, complained when the government raised its recommended vitamin E intake by 50 %, because it wasn't supported by new data, and because millions of people get only 10 mg per day and "are healthy." But he has been taking 200 mg daily (plus aspirin) for many years. He apparently doesn't have very much confidence in the ideas he advocates publicly.

Water

Swelling, Tension, Pain, Fatigue, Aging

Ray Peat's Newsletter, 2009

I have spoken to many people who believe they should drink "8 glasses of water every day," in addition to their normal foods, even if they don't feel thirsty. Many doctors still recite this dangerous slogan, but the addition of the qualifying phrase, "or other liquids," has become common.

The amount of water a person needs is extremely variable, depending on things such as metabolic rate, activity, and the temperature and humidity of the air. Working hard in hot, dry weather, it's possible to drink more than two quarts per hour for more than eight hours, without forming any urine, because all of the water is lost by evaporation. But in very hot, humid weather, a person with a low metabolic rate can be endangered by the smallest amount of water.[1]

Most foods contain a considerable amount of water, usually more than 70% of their weight, and some water is produced in cells by metabolism. The function of water in the organism has been mystified and neglected because of some deeply rooted cultural images of the nature of organisms and their cellular make-up.

One silly image that has been perpetuated by schools and textbooks is that biochemistry consists of chemical reactions that occur in substances dissolved in water, and that the water is retained by cells because they are enclosed by an oily membrane, and because of the osmotic forces produced by the dissolved substances. Most grade school kids have seen an osmometer made from an egg, in which the egg causes a column of water to rise, and have heard the explanation that this has something to do with the way cells work. Membrane pumps are invoked to explain the differences in solute concentrations and "osmotic pressure" inside and outside cells. The story is that invisible things on the surface of a cell (in its "membrane") force dissolved molecules to move in ways that they wouldn't move spontaneously by diffusion, and that water passively follows the "actively transported" solutes. But the evidence shows that both water and its solutes are regulated by the bulk phase of the cell, not its surface.

In some cultural settings, animism has a kind of charm (water sprites, and such), but in the culture of medicine and biology, the animistic conceptualization of cells and their mechanisms has been very destructive, because it gets in the way of coherent understanding of physiology. Practically every disease would be approached differently if the physiology of water and ions were allowed to advance beyond the animistic doctrines of mainstream medicine, such as the "membrane pumps." If all the substances that are said to be "actively transported" by pumps into, or out of, cells are considered, the amount of energy required to operate the pumps is at least 15 times larger than the total energy available to cells. "Specific" pumps are commonly invoked even for novel synthetic chemicals, to explain their unequal distribution, inside and outside cells. In many biological situations water is ignored, but when it becomes an issue, its distribution is usually mechanistically subordinated to the solutes that are actively "pumped."

Cells aren't osmometers, in the sense the textbooks say. They do control their water content, but no "membrane pumps" are needed. It's more accurate to think of the water of cells as being "dissolved in cells," somewhat the way water is contained in jello or boiled eggs. The cell controls its hydration by the processes that control its structure, its metabolism, and movements, because water is part of its deepest structures and essential functions. The cell's adjustments to changes of hydration and volume appear to be regulated by contractile proteins and energy metabolism.[2]

Any stress or energy deficit that disturbs cellular structure or function disturbs the interactions among water, proteins, and other components of the cell. Excitation causes a cell to take up extra water, not by osmosis resulting from an increase in the concentration of solutes in the cell, or because the membrane has become porous, but because the structural proteins of the cell have momentarily increased their affinity for water.

This increased affinity is similar to the process that causes a gel to swell in the presence of alkalinity, and it is related to the process called electroosmosis, in which water moves toward a higher negative charge. Intense excitation or stress increases the cell's electrically negative charges, and causes it to become more alkaline and to swell. Swelling and alkalinity cause the cell to begin the synthesis of DNA, in preparation for cell division. Mitogens and carcinogens, including estrogen, cause cells to become alkaline and to swell, and substances that block the

cell's alkalinization (such as the diuretics acetazolamide and amiloride) inhibit cell division. Prolonged alkaline stress alone can cause malignant transformation of kidney cells.[3]

The general idea of "stress" is useful, because it includes processes such as fatigue, osmotic pressure changes, disturbed pH, and the enzyme changes that follow, producing substances such as lactic acid, nitric oxide, polyamines, estrogen, serotonin, and many more specific mediators. But paying attention to the physical factors involved in a stress reaction is important, if we are to see the organism integrally, rather than as a collection of "specific biological mechanisms," involving things like the pixie-powered "membrane pumps."

When a cell shrinks under hyperosmolar conditions, its metabolism becomes catabolic, breaking down proteins and glycogen, and sometimes producing lactic acid, which results in an alkaline shift, increasing the cell's affinity for water, and causing it to return to normal size. A slight degree of hyperosmolarity increases the cell's metabolic rate.

Swelling in hypo-osmolar conditions, i.e, with an excess of water, is anabolic, leading to cellular proliferation, and inhibiting the breakdown of protein and glycogen.

Respiring cells are always producing some water, by transferring hydrogen from fuel molecules to oxygen. Respiration also produces carbon dioxide, which in itself is a Lewis acid (meaning that it binds electrons, rather than releasing protons), that associates with cellular proteins, acidifying them in the process. A large amount of carbon dioxide can exist inside cells in the bound form. Acidified cytoplasm (like any other mostly acidic polymer-gel) releases water and sodium. (This process is physically analogous to the process of flushing a water softener with salt, or a demineralizer with acid, to reactivate it.)

Besides binding with the cytoplasm, the carbon dioxide can be changed into carbonic acid, by chemically combining with water. Carbonic acid is hydrophilic, and so it quickly leaves the cell, taking with it some of the oppositely charged ions, such as calcium and sodium. The formation of carbonic acid, which is constantly streaming out of the respiring cell, causes some water and some positively ionized metals to leave the cell, in an "active" process, that doesn't require any mysterious pumps.

As the blood passes through the lungs, carbon dioxide leaves the system, and as carbonic acid is converted to carbon dioxide, water is left

behind in the blood, along with the counterions (of alkaline metals or earths), accounting for slight differences in pH and osmolarity between the bloodstream and the tissue cells. Some experiments suggest that the normal osmolarity of various tissues is 2 or 3 times higher than that of the blood, which is called "isosmolar" or isotonic.

The kidneys adjust the osmolarity of the blood by allowing water and solutes to leave the bloodstream, in proportions that usually keep the body fluids in balance with cells. The kidneys are able to compensate for many of the imbalances produced by stress and inappropriate diets, for example by forming ammonia and carbon dioxide, to compensate for imbalances in the alkalis and acids that are being delivered to the blood by other organs. Because of the kidneys' great ability to regulate the flow of solutes between the blood and the forming urine, the "membrane pumps" have great importance for medical nephrologists. But the more extreme the "active transport" is, the more obvious it becomes that processes other than "membrane pumps" are responsible.

Some lizards and sea birds have glands near their noses that are called salt glands, because of their ability to secrete salt. The salt gland is probably the most extreme case of active transport, but its physiology is very similar to the physiology of any other secretory gland or membrane, such as tear glands and sweat glands. The mechanism of salt excretion in these glands should really settle the issue of how active transport works, but most nephrologists, oculists, and medical researchers in general aren't interested in salt glands.

Carbon dioxide is the driving force in the salt gland. The constant formation of CO_2, and its loss into the air, allows a high concentration of salt to be excreted. Blocking the interchange of CO_2 and carbonic acid, with acetazolamide, or inhibiting the formation of CO_2, prevents the excretion of salt.

Since respiratory metabolism, governed by the thyroid hormone, is our main source of carbon dioxide, it's obvious that thyroid deficiency should impair our ability to regulate water and solutes, such as salt. An organism that illustrates this function of thyroid is the young salmon, when it leaves a freshwater river to begin its life in the ocean. As it converts its physiology to tolerate the salty environment, its thyroid hormone surges. When it's mature, and returns to the fresh water to spawn, its prolactin rises sharply. In experiments with rodents, it

has been found that drinking a large amount of water increases their prolactin, but the same amount of water, with added salt, doesn't.

Hypothyroidism is typically associated with increased prolactin secretion. Hypothyroid people typically retain water, while losing salt, so the hypothyroid state is analogous to the salmon that has returned to the river, and to the mice that drink too much salt-free water.

The typical hypothyroid person loses salt rapidly in the urine (and probably in the sweat, too, though that is usually diagnosed as cystic fibrosis), and retains water, diluting the urine less than normal. The reduced production of carbon dioxide, with increased susceptibility to producing lactate and ammonium, causes the cells to be more alkaline than normal, increasing their affinity for water. The rise of estrogen that usually accompanies hypothyroidism also increases intracellular pH, loss of sodium, and over-hydration of the blood.

Hypothyroid muscles typically retain excess water, and fatigue easily, taking up more water than normal during exertion. In childhood, mild hypothyroidism often causes the leg muscles to swell and ache in the evenings, with what have been called "growing pains." When the problem is more extreme, all the skeletal muscles can become very large (Hoffman syndrome), because of the anabolic effect of over-hydration. Enlargement of any muscle can result from the excessive hydration produced by thyroid deficiency, but when it happens to the muscles behind the eyes,[4] it often leads to a diagnosis of hyperthyroidism, rather than hypothyroidism.

The little kids with the Hoffman syndrome don't have the bloated myxedematous appearance that's often associated with hypothyroidism. They look athletic to a ridiculous degree, like miniature body-builders. But after a few weeks of treatment with thyroid, they regain the slender appearance that's normal for their age. The swollen state actually supports enlargement of the muscle, and the cellular processes are probably closely related to the muscle swelling and growth produced by exercise. The growth of the muscle cell during swelling seems to be the result of normal repair processes, in a context of reduced turnover of cellular proteins.

The people who believe in membrane pumps that maintain normal solute distributions by active transport know that the pumps would require energy (far more than the cell can produce, but they don't confront that issue), and so their view requires that they assign a great part of the

cell's resources just to maintaining ionic homeostasis, and the result of that is that they tend to neglect the actual energy economy of the cell, which is primarily devoted to the adaptive renewal of the cell structure and enzyme systems, not to driving the systems that don't exist.

The "anabolic" balance of the swollen cell is the result of decreased turnover of the cell's components. The higher rate of metabolism produced by adequate thyroid function maintains a high rate of renewal of the cell's systems, keeping the cell constantly adjusted to slight changes in the organism's needs. The evidence of a high rate of bone turnover is sometimes taken as evidence that thyroid can cause osteoporosis.

Later, in a more mature person, chronically fatigued and painful muscles that at one time would have been diagnosed as rheumatism, may be diagnosed as fibromyalgia. Most doctors are reluctant to prescribe thyroid supplements for the problem, but the association of elevated prolactin with the muscle disorder is now generally recognized.

The hypo-osmolar blood of hypothyroidism, increasing the excitability of vascular endothelium and smooth muscle, is probably a mechanism contributing to the high blood pressure of hypothyroidism. The swelling produced in vascular endothelium by hypo-osmotic plasma causes these cells to take up fats, contributing to the development of atherosclerosis. The generalized leakiness affects all cells (see *Leakiness* newsletter), and can contribute to reduced blood volume, and problems such as orthostatic hypotension. The swollen endothelium is stickier, and this is suspected to support the metastasis of cancer cells. Inflammation-related proteins, including CRP, are increased by the hypothyroid hyperhydration. The heart muscle itself can swell, leading to congestive heart failure.

Some of the nerve problems associated with hypothyroidism (e.g., carpal tunnel syndrome and "foot drop") are blamed on compression of the nerves, from swelling of surrounding tissues, but the evidence is clear that hypothyroidism causes swelling in the nerve cells themselves. For example, in hypothyroidism, nerves are slow to respond to stimulation, and their conduction of the impulse is slow. These changes are the same as those produced by hyper-hydration caused by other means. Hypothyroid nerves are easily fatigued, and fatigued nerves take up a large amount of water. Swelling of the spinal cord is probably responsible for the "spinal stenosis" commonly seen in domestic animals and people;

the mobility of intracellular water molecules is distinctly increased in patients with compression of the spinal cord.[5,6]

The hyperhydration of hypothyroidism has been known to cause swelling and softening of cartilage, with deformation of joints, but somehow it has never dawned on surgeons that this process would lead to deformation of intervertebral disks.

It has been known for a long time that hyperhydration can produce seizures; at one time, neurologists would test for epilepsy by having the patient drink a pint of water. Although there are many reasons to think that the hyperhydration produced by hypothyroidism is a factor in epilepsy, physicians have been very reluctant to consider the possibility, because they generally think of thyroid hormone as a stimulant, and believe that "stimulants" are necessarily inappropriate for people with epilepsy.

While it's true that the thyroid hormone increases sensitivity to adrenaline, its most noticeable effect is in improving the ability to relax, including the ability to sleep soundly and restfully. And it happens that increasing norepinephrine (the brain's locally produced form of adrenaline) helps to prevent seizures.[7]

Cell swelling increases the sensitivity of nerves, and hyperosmotic shrinkage lowers their sensitivity. Increasing carbon dioxide helps to reduce the hydration of tissue (for example, the hydration and thickness of the cornea are decreased when carbon dioxide is increased), and increasing carbon dioxide is known to inhibit epileptic seizures. Another diagnostic trick of neurologists was to have the patient hyperventilate; it would often bring on a seizure. The diuretic acetazolamide, which increases the body's carbon dioxide and reduces water retention, is very effective for preventing seizures.

The sleep-inducing effect of salty food is probably related to the anti-excitatory effects of hyperosmolarity, of adequate thyroid function, and of carbon dioxide.

Degenerative diseases, especially cancer, heart disease, and brain diseases, are less prevalent in populations that live at a high altitude. When oxygen pressure is low, the lungs lose carbon dioxide more slowly, and so the amount of carbon dioxide retained in the body is greater. If the basic problem in hypothyroidism is the deficient production of carbon dioxide causing excessive loss of salt and retention of water, resulting in hypo-osmotic body fluids, then we would expect people at high altitude

to have better retention of salt, more loss of water, and more hypertonic body fluids. That has been observed in many studies. The increased rate of metabolism at altitude would be consistent with the relatively active "catabolism" of the slightly hyperosmotic condition.

After the drug companies began, in the late 1950s, marketing some newly discovered (thiazide) diuretics, which cause sodium to be lost in the urine, their advertising campaigns created a cultish belief that salt caused hypertension. They convinced a whole generation of physicians that pregnant women should limit salt in their diet, take a diuretic preventively, and restrict calories to prevent "excessive" weight gain. Millions of women and their babies were harmed by that cult.

Pre-eclampsia and pregnancy toxemia have been corrected[8] by both increased dietary protein and increased salt, which improve circulation, lower blood pressure, and prevent seizures, while reducing vascular leakiness. The effectiveness of increased salt in pre-eclampsia led me to suggest it for women with premenstrual edema, because both conditions typically involve high estrogen, hyponatremia, and a tendency toward hypo-osmolarity. Estrogen itself causes sodium loss, reduced osmolarity, and increased capillary leakiness. Combined with a high protein diet, eating a little extra salt usually helps to correct a variety of problems involving edema, poor circulation, and high blood pressure.

The danger of salt restriction in pregnancy has hardly been recognized by most physicians, and its danger in analogous physiological situations is much farther from their consideration.

One of the things that happen when there isn't enough sodium in the diet is that more aldosterone is synthesized. Aldosterone causes less sodium to be lost in the urine and sweat, but it achieves that at the expense of the increased loss of potassium, magnesium, and probably calcium. The loss of potassium leads to vasoconstriction, which contributes to heart and kidney failure and high blood pressure. The loss of magnesium contributes to vasoconstriction, inflammation, and bone loss. Magnesium deficiency is extremely common, but a little extra salt in the diet makes it easier to retain the magnesium in our foods.

Darkness and hypothyroidism both reduce the activity of cytochrome oxidase, making cells more susceptible to stress. A promoter of excitotoxicity, ouabain, or a lack of salt, can function as the equivalent of darkness, in resetting the biological rhythms.[9,10]

Bone loss occurs almost entirely during the night, and the nocturnal rise in cortisol and prolactin has strongly catabolic effects, but many other pro-inflammatory substances also rise during the night, and are probably the basic cause of the increased catabolism. Increased salt in the diet appears to improve some aspects of calcium metabolism, such as reducing parathyroid hormone and increasing ionized calcium, when the diet is deficient in calcium.[11]

The kidneys can produce large amounts of carbon dioxide and ammonia, in the process of preventing the loss of electrolytes, while allowing acid to be lost in the urine. The ammonia is produced by the breakdown of protein. During stress or fasting, the loss of tissue protein can be minimized by supplementing the minerals, potassium, sodium, magnesium, and calcium. Salt restriction can cause aldosterone to increase, and excess aldosterone causes potassium loss, and increases the use of protein to form ammonia.[12–14]

Aldosterone secretion increases during the night, and its rise is greater in depressed and stressed people. It inhibits energy metabolism, increases insulin resistance, and increases the formation of proinflammatory substances in fat cells.[15] During aging, salt restriction can produce an exaggerated nocturnal rise in aldosterone.

During the night, there are many changes that suggest that the thyroid functions are being blocked, for example a surge in the thyroid stimulating hormone, with T_4 and T_3 being lowest between 11 PM and 3 AM,[16] while temperature and energy production are at their lowest. This suggests that the problems of hypothyroidism will be most noticeable during the night.

Rheumatoid arthritis and asthma are two inflammatory conditions that are notoriously worse during the night. Melatonin has been reported to be higher in patients with severe asthma and rheumatoid arthritis, and to promote the secretion of a variety of other pro-inflammatory substances. The peak of melatonin secretion is followed by the peak of aldosterone, and a little later by the peak of cortisol.

The use of bright light (which suppresses melatonin) to treat depression probably helps to inhibit the production of aldosterone, which is strongly associated with depression.

Both aldosterone and melatonin can contribute to the contraction of smooth muscle in blood vessels. Constriction of blood vessels in the kidneys helps to conserve water, which is adaptive if blood volume has

been reduced because of a sodium deficiency. When blood vessels are inappropriately constricted, the blood pressure rises, while organs don't receive as much blood circulation as they need. This impaired circulation seems to be what causes the kidney damage associated with high blood pressure, which can eventually lead to heart failure and multiple organ failure.

Progesterone, which helps to maintain blood volume (partly by preventing vascular leakiness, preventing excessive sodium loss and by supporting albumin synthesis) antagonizes aldosterone. Aldosterone antagonists are now being recognized as effective treatments for hypertension, water retention, congestive heart failure, arrhythmia, diabetes, kidney disease, and a great variety of inflammatory problems. (Synthetic drugs to antagonize aldosterone are most effective when they are most like natural progesterone.) Since aldosterone contributes to fibrosis of the heart and kidneys (nephrosclerosis), progesterone, the "antifibromatogenic steroid," should be helpful for those problems that have been considered irreversible. Aldosterone appears to contribute to the hyperglycemia of diabetes itself, and not just to its complications, by interfering with the interactions of insulin and cortisol.[17]

One of progesterone's fundamental actions is to cause estrogen "receptors" to disintegrate; hypertonicity has this effect in some situations. Estrogen's effects are largely produced by increased tissue hydration.

Aldosterone causes cells to take up sodium, while increasing their pH, i.e., raising their alkalinity.[18] Intracellular sodium has long been known to be a factor, along with swelling and alkalinity, in stimulating cell division.[19] A lack of salt stimulates the formation of serotonin, which in turn stimulates aldosterone synthesis—that is, a sodium restricted diet activates processes that cause cells to take up sodium inappropriately, in a situation reminiscent of the calcium deficient diet causing inappropriate calcification.

Aldosterone, like stress or hypo-osmolarity, activates the enzyme (ODC) which produces the polyamines, that promote cell division, and that can probably account for some of the harmful effects of excessive aldosterone.

Eating salty food around bedtime usually has a sleep-inducing effect, and it helps to maintain blood volume (which tends to decrease during the night), and to restrain the nocturnal rise of aldosterone, and other indicators of stress or inflammation. Eating gelatin, which lacks trypto-

phan, will reduce the formation of serotonin, and is likely to limit the formation of aldosterone.

Pregnenolone can sometimes very quickly allow swollen tissues to release their water. This function is probably closely related to its antifibromatogenic function, since swelling and leaking set the stage for fibrosis.

Hyperosmotic sodium chloride solutions (e.g., 7.5 %) are being used more often for treating trauma and shock, because the concentrated solution increases blood volume by removing water from the extravascular spaces, unlike the "isotonic" saline (0.9 % sodium chloride), which usually adds to the edema by leaking out of the blood vessels.

A 5 % sodium chloride solution is effective for promoting healing of damaged corneas, and solutions of 5 % to 10 % sodium chloride are effective for accelerating the healing of wounds and ulcers. Other hypertonic solutions, for example glucose or urea, have been used therapeutically, but sodium chloride seems to be the most effective in a variety of situations.

Thyroid hormone, by maintaining oxidative metabolism with the production of carbon dioxide, is highly protective against excessive water retention and loss of sodium and magnesium.

Sometimes doctors recommend that constipated people should drink extra water, "to soften the stool." The colon is where water is removed from the intestinal contents, and when it is inflamed, it removes too much water. Several decades ago, it was recognized[20] that hypertonic saline, given intravenously, would stimulate intestinal peristalsis, and could be used to treat paralytic ileus and intestinal obstruction.

When water is taken orally, it is absorbed high in the intestine, long before it reaches the colon, so the recommendation to drink water for constipation can produce a situation that's the opposite of intravenous hypertonic saline, by diluting the blood. Using a hypertonic salt solution as an enema can have the same beneficial effect on the intestine as the intravenous treatment.

Constipation physiology is probably analogous to the physiology of congestive heart failure, in which muscles are weakened and fatigued by swelling.

In recent decades, the prevalence of congestive heart failure has increased tremendously, so that it is now often called an epidemic. Hyponatremia (too little salt, or too much water) is a recognized "risk

factor" for congestive heart failure. In the failing heart, the muscle cells are swollen, causing the heart wall to stiffen, weakening its ability to pump. Osmotically shrinking the cells can restore their function.

The swollen heart, like any muscle, loses the ability to quickly and completely relax, and so it doesn't fill adequately between contractions. Elastic tissues, such as arteries and lungs, stiffen when they are overhydrated, losing their normal functions. In small blood vessels, swelling narrows the channel, increasing resistance to the flow of blood.

When people force themselves to drink a certain amount of water every day, even when they don't feel thirsty, they are activating complex adaptive processes unnecessarily. Thirst is the best guide to the amount of fluid needed.

When extra water consumption is combined with a low salt diet—as physicians have so often recommended—a healthy person can adapt easily, but for a hypothyroid person it can have disastrous effects.

When Energy Fails

Edema, Heart Failure, Hypertension, Sarcopenia, etc.

Ray Peat's Newsletter, 2013

More than 100 years ago the idea of a morphogenetic field was proposed by A.G. Gurwitsch, as a way to explain the orderly movements of cells in embryos and growing tissues, and to understand the principles that cause cells to change appropriately when their location in the organism changes. For 30 years, the concept guided research in embryology, but also led to important discoveries in the biology of cancer, aging, wound repair, and other important areas. But by the late 1940s, a more abstract approach to biology, based on the gene doctrine of Mendel and Weismann, took charge of academic and governmental biological research. This ideology at first said that organisms are determined by unchanging units of inheritance, "genes," and later when genes were found to be susceptible to mutation, the changes were said to be always random. The Central Dogma of the ideology was that any meaningful, adaptive changes that occur in an organism can't influence the genes. For many years, adaptive changes were said to be nothing but changes in the size or function of existing cells, because the cells of the major organs of the body were supposed to be created before birth, or in infancy.

Besides the purely ideological commitment to the theory of genes, there were other influences that contributed to the culture of Molecular Biology. People learned histology from slides or pictures made by killing, hardening, dehydrating, and slicing parts of organisms. Biochemists studied the chemistry of life mainly by grinding cells or tissues, and extracting water-soluble materials to study the actions of enzymes on various materials. These unrealistic artifacts filled the textbooks and the minds of generations of biologists and physicians. The culture of molecular biology used these artifacts to create theories of embryology and physiology, and holistic ideas such as the developmental field were disregarded.

The mental image of a living organism that has been created by that culture is simply wrong. The concept of a developmental field is essential for understanding embryology, because things that exist on a scale bigger than molecules and cells govern the functions of the molecules and cells, and the principles of embryology don't arbitrarily stop operating at birth,

but can be seen to continue operating during maturity and aging. The interactions of cells with their environment are different at different stages of life, but there are commonalities that are extremely important.

The processes that govern the pregnant woman's blood circulation, in sustaining the development of a fetus, are very similar to the processes that govern anyone's blood circulation, providing for the maintenance and renewal of all the body's organs. The common problems of pregnancy involving the circulatory system can provide insights into the problems of the various organs that have been the focus of the medical specialties, and to some basic medical issues, including aging, obesity, and inflammation.

The development of a fertilized egg into an embryo consumes energy at a very high rate, and the way the embryo develops depends on a continuously adequate supply of oxygen and sugar, and other nutrients. The intense flow of energy through each stage of a developing structure shapes the following stage. The necessary energy and materials are provided abundantly by the mother's blood. When the development has advanced far enough to make life possible outside the uterus, energy will be used more slowly, for growth, maintenance, and renewal of tissues.

Failure to renew cells and tissues leads to the loss of function and substance. Bones and muscles get weaker and smaller with aging. Diminished bone substance, osteopenia, is paralleled, at roughly the same rate, by the progressive loss of muscle mass, sarcopenia (or myopenia). The structure of aging tissue changes, with collagen tending to fill the spaces left by the disappearing cells. It's also common for fat cells to increase, as muscle cells disappear.

When conditions are ideal, as during healthy development in the uterus, tissue damage is corrected by the multiplication of cells to replace any that were lost. But when conditions are less perfect, injuries are imperfectly repaired, usually with highly collagenous scar tissue bridging the area that was destroyed. During this imperfect repair, there is inflammation, which apparently exists to the extent that the substances needed for regeneration are lacking. For example, when oxygen is lacking, lactic acid is likely to be produced, along with increases of pro-inflammatory regulators such as histamine and serotonin, leading to the loss of many important proteins and functions, and the over-production of collagen instead.

Since cellular renewal of tissues, in a healthy individual, is a constant process, we can think of the metabolic rate of a healthy adult as just what is needed to sustain this constant, limited sort of regeneration, but not quite intense enough to produce scarless healing of a wound (without special intervention).

If something reduces the systemic ability to produce energy, there will be a gap between the available energy and the energy needed for the constant turnover of cells in each tissue and organ, and a generalized inflammation will develop. The replacement of cells will be slowed, and the organism will mobilize the processes used for producing scar tissue, producing an excess of collagen, filling the spaces left by the lost cells.

We are susceptible to many things that interfere with energy production—the substitution of iron for copper in the respiratory enzyme, the absorption of endotoxin, the accumulation of PUFA, a deficiency of thyroid hormone, the formation of increased amounts of nitric oxide, serotonin, and histamine, etc. Different environments will condition the way the defensive mechanisms of inflammation are produced.

Toxemia of pregnancy, or preeclampsia, is a state of generalized inflammation, and some of the causes and remedies are known. Despite the predominance of crazy genetic theories of preeclampsia in 20th century medical literature, there was clear evidence (reviewed by Tom Brewer, Douglas Shanklin, and Jay Hodin) that it was caused by malnutrition, and that it could be cured by adequate protein, salt, and calcium.

The old medical practice of restricting salt intake during pregnancy was an important factor in causing it, so it's interesting to look at the effects of salt restriction as a treatment for hypertension.

The pregnant woman's blood volume expands, to permit the supply of energy to match the needs of the embryo. If the blood volume doesn't increase, or if it decreases, as in pregnancy toxemia, her blood pressure will increase. Typically, the decrease of blood volume is accompanied by an increase in the extracellular fluid, edema, resulting from leakage of fluid through the walls of the capillaries, and albumin appears in the urine as it leaks through the capillaries in the kidneys. The amount of blood pumped by the heart, however, is increased in toxemia,[1] showing that the increased blood pressure is at least partially compensating for the smaller volume of blood.

A similar situation, reduced blood volume and edema, can be seen[2] in "essential hypertension," the "unexplained" high blood pressure that occurs more often with increasing age and obesity. At the beginning of "essential hypertension," the amount of blood pumped is usually greater than normal.

In both situations, preeclampsia and essential hypertension, there is an increased amount of aldosterone, an adrenal steroid which allows the kidneys to retain sodium, and to lose potassium and ammonium instead. A restriction of salt in the diet causes more aldosterone to be produced, and increased salt in the diet causes aldosterone to decrease. One effect of aldosterone is to increase the production of a substance called vascular endothelial growth factor, VEGF, or vascular permeability factor, which causes capillaries to become leaky, and causes new blood vessels to grow.

While increased salt in the diet tends to lower both aldosterone and VEGF, reducing the leakiness of blood vessels, sodium also has a direct effect that tends to prevent the leakage of water and albumin out of the blood vessels, helping to maintain the blood volume which is needed to perfuse the kidneys, preventing them from producing signals to increase blood pressure and aldosterone. There is a large amount of albumin in the blood serum, and sodium ions associate with the negative electrical charges on the albumin molecule. This association causes the complex of albumin and sodium to attract a large amount of water, that is to exert osmotic or oncotic pressure. This oncotic pressure causes any excess extracellular water to be attracted into the blood vessels, preventing edema while maintaining the blood volume. When there is too little sodium, the albumin molecule itself easily leaves the blood stream along with the water.

Instead of considering the significance of sodium's effects on albumin, aldosterone, and VEGF, textbooks have often talked about the factors that "pump" sodium, and factors that specifically regulate the movement of water. Experiments in which an excess of aldosterone is combined with a high salt intake produce increased blood pressure, and—by invoking various genes—salt is said to cause hypertension in certain people. This reasoning is hardly different from the reasoning of the drug companies in the 1950s who said that since women with toxemia have hypertension and edema, they should be treated with a diuretic and a low salt diet, to eliminate water and to reduce blood pressure.

The physiological loss of sodium occurs when energy metabolism fails, as in diabetes, hypothyroidism, hyperestrogenism, and starvation. What these conditions have in common is an increased level of free fatty acids in the blood. Increased free fatty acids impair the use of glucose. The consumption of carbohydrate, like an increase of thyroid hormone, insulin, or progesterone, increases the retention of sodium; fructose is the most effective carbohydrate.[3]

The loss of sodium is often accompanied by the retention of water, reducing the osmotic pressure of the body fluids. The leakiness of blood vessels allows the extracellular fluid volume to increase, as understood in the standard definition of edema. However, when this fluid is hypo-osmotic, it will enter cells, causing them to swell. Cell swelling excites cells,[4,5] and can kill them if they are unable to produce enough energy to restore their original volume, by measures including the excretion of amino acids and potassium. Both low sodium (hyponatremia) and low osmotic pressure stimulate the adrenergic nervous system.

The increase of adrenalin, caused by a deficiency of sodium, is one of the factors that can increase blood pressure; if the tissues's glycogen stores are depleted, the adrenalin will mobilize free fatty acids from the tissues, which tends to inhibit energy production from glucose, and to increase leakiness. After I had read Tom Brewer's work on preventing or curing preeclampsia with added salt, I realized that the premenstrual syndrome involved some of the features of preeclampsia (edema, insomnia, cramps, hypertension, salt craving), so I suggested to a friend that she might try salting her food to taste, instead of trying to restrict salt to "prevent edema." She immediately noticed that it prevented her monthly edema problem. For several years, all the women who tried it had similarly good results, and often mentioned that their sleep improved. I mentioned this to several people with sleep problems, and regardless of age, their sleep improved when they ate as much salt as they wanted. Around that time, several studies had shown that salt restriction increases adrenalin, and one study showed that most old people on a low sodium diet suffered from insomnia, and had unusually high adrenalin. When they ate a normal amount of salt, their adrenalin was normalized, and they slept better.

It's very common for physicians who are aware of progesterone's "anti-aldosterone" activity to think that both estrogen and progesterone are responsible for the increased risk of sodium loss in women, especially

during pregnancy, but Hans Selye demonstrated that progesterone will normalize sodium retention even when there is no aldosterone at all, following removal of the adrenal glands. It is estrogen which is responsible for the dangerous loss of sodium.

The ratio of estrogen to progesterone—regardless of age or gender—is an important factor in regulating minerals and water, cell energy metabolism, and blood pressure. The ratios of many other regulatory substances (including serotonin/dopamine, glucagon/insulin, and aldosterone/cortisol+progesterone) vary according to the quality of the individual's level of adaptation to the environment. Improving the environment can shift the ratio in the direction of restoration, rather than mere survival.

Gershom Zajicek and his colleagues have demonstrated an organized renewal of tissues, in which new cells are born with the division of stem cells, and "stream" away from their origin as they mature, and finally are shed or dissolved. A few studies have demonstrated a similar kind of migration of new cells in the brain,[6,7] a process which differs by the absence of systematic dissolution of mature brain cells. While Zajicek has demonstrated the conversion of one kind of cell, such as a pancreatic ductal epithelial or acinar cell into insulin-secreting beta cells, other researchers have shown that after injury to the pancreas beta cells can be formed from glucagon-secreting alpha cells, as well as from other beta cells.

Stress, increasing the need for energy, increases the formation of cortisol and free fatty acids when glucose isn't available, and those—while they provide alternative sources of energy—interfere with the ability to produce energy from glucose. Free fatty acids and cortisol can cause the insulin-secreting beta cells to die. Glucose, and insulin which allows glucose to be used for energy production, while it lowers the formation of free fatty acids, promotes the regeneration of the beta-cells. Although several research groups have demonstrated the important role of glucose in regeneration of the pancreas, and many other groups have demonstrated the destructive effect of free fatty acids on the beta cells, the mainstream medical culture still claims that "sugar causes diabetes."

In the adrenal glands, renewing cells stream from the capsule on the surface of the gland toward the center of the gland. The first cells to be produced in a regenerating gland are those that produce aldosterone, the next in the stream are the cortisol producing cells, and the last to

be formed are the cells that produce the sex hormones, the androgens including DHEA, and progesterone. In aging, after the age of thirty, the renewal slows, but the dissolution of the sex hormone zone continues, so the proportion shifts, increasing the ratio of the aldosterone and cortisol producing cells to the layer that produces the protective androgens and progesterone.[8]

Even before aldosterone was identified, progesterone's role in regulating the salts, water, and energy metabolism was known, and after the functions of aldosterone were identified, progesterone was found to protect against its harmful effects, as it protects against an excess of cortisol, estrogen, or the androgens. New anti-aldosterone drugs are available that are effective for treating hypertension and heart failure, and their similarity to progesterone is recognized.

While stress typically causes the adrenal glands to produce cortisol, extreme stress, as described by Hans Selye, damages the adrenal cortex, and can cause the cells to die, leading to the death of the animal. There is evidence that it is the breakdown of unsaturated fatty acids that causes damage to the adrenal cortex in extreme stress. Although many factors influence the production of the adrenal steroids, arachidonic acid, even without being converted to prostaglandins, is an important activator of aldosterone synthesis. Adrenalin, produced in response to a lack of glucose, liberates free fatty acids from the tissues, so when the tissues contain large amounts of the polyunsaturated fatty acids, the production of aldosterone will be greater than it would be otherwise.

The continuing accumulation of polyunsaturated fats in the tissues is undoubtedly important in the changing relationship between the pancreas and the adrenal glands in aging. Aspirin, which is antilipolytic, decreasing the release of free fatty acids, as well as inhibiting their conversion to prostaglandins, lowers the production of stress-induced aldosterone, and helps to lower blood pressure, if it's taken in the evening, to prevent the increase of free fatty acids during the night. Aspirin increases insulin sensitivity. A low salt diet increases the free fatty acids, leading to insulin resistance, increasing free fatty acids in the blood, and contributing to atherosclerosis.[9–12]

The same factors that support or interfere with cellular renewal in the pancreas and adrenal glands have similar effects in the bones, skin, skeletal and heart muscle, nervous system, liver, and other organs. In every case, the local circulation of blood is influenced by both local and

systemic factors. The loss of control over the water in the body is the result of energy failure, and hypertension is one of the adaptations that helps to preserve or restore energy production.

Lowering inflammation and the associated excess of free fatty acids in the blood, and improving the ability to oxidize glucose, will lower blood pressure while improving tissue renewal, but lowering blood pressure without improving energy production and use will create new problems or intensify existing problems. After 40 years the medical profession quietly retreated from their catastrophic approach to pregnancy toxemia, but in the more general problem of essential hypertension, the mistaken ideology is being preserved, even as less harmful treatments are introduced. That ideology prevents a comprehensive and rational approach to the problems of stress and aging.

A Biophysical Approach to Altered Consciousness

Journal of Orthomolecular Psychiatry, Volume 4, Number 3, 1975

ORDINARY chemical and biological thinking tends to emphasize special functions at the expense of general and organismic processes. I want to suggest some of the ways in which "physical state" ideas can bring generality to the complex biochemistry of consciousness and behavior.

I use the phrase "physical state" to suggest that life, and its pathological and evolutionary modifications, can profitably be considered as a special "state of matter." The liquid crystalline state, with its various degrees of order, is a good example of another special state of matter. Living material is peculiar in being able to use external energy to increase its order without having to reduce its temperature; nerves and muscles, for example, consume ATP and CrP when they "fire," and they are able to return to their resting, sensitive state as long as energy is available. These active and resting states differ in various ways, such as preference for sodium or potassium ions, volume,[1] and even in the freedom and average alignment of their water molecules.[2,3]

These two states, active and resting, can also be characterized, respectively, as hydrophilic and hydrophobic;[4,5] as sodium-loving, and potassium-loving; as inefficient and efficient.[6]

The all-or-nothing impulse of a neuron is not the only known or plausible[7,8] mechanism of nervous communication. Nevertheless, all forms of cell conductivity are subject to modification by any process which shifts the equilibrium in either direction from the normal resting state—toward excessive "readiness," or toward incomplete restoration of the resting sensitive state. Russian biologists are most active in studying the changes that occur in tissue exhaustion[9]—e.g., increased dye uptake, decreased electrical conductivity—but Crile[10] and others several decades ago discovered some of the basic electrical properties of tissue related to consciousness.

If such tissue conductivity is a gross aspect of the kind of conduction which maintains our perceptual model of the world, we would expect a disturbed "state equilibrium," through its effect on conductivity, to alter our perceptions in general ways, such as spatial expansion or foreshortening.[11,12] Since such perceptual changes are common in depression,

mania, "schizophrenia," paranoia, delirium, etc., this "physical state" theory would predict that ionic and metabolic intervention would be possible to relieve those conditions. There is a long history of "resonance" models of consciousness, and some of them are highly relevant to this holistic and physical approach.[13,14]

There are many examples of gel hysteresis, in which a transition in one direction is easier than a return to its previous state. This seems to be what happens in the cornea after a prolonged riboflavin deficiency: even very high doses of riboflavin fail to restore its concentration in the cornea to a normal level, as if its solubility in the corneal gel had been reduced.

The monovalent alkali metal ions "bind" to themselves more water molecules as their radius becomes smaller, i.e., in the series rubidium, potassium, sodium, lithium. In this sense, lithium can be considered to be "super-sodium," and rubidium would be "super-potassium." Their affinities for cell proteins are apparently determined by their own radius and by the charge concentration of sites on the proteins.[15,16] The presence of these ions in turn stabilizes the conformation of the protein-water system in such a way that the charge concentration of the protein sites continues to favor those ions, barring the intervention of a stronger influence. These stronger influences may include powerfully adsorbed polyions such as ATP,[16] or certain changes in amino acids, or disturbed electronic conditions.[17] Glutamic acid increases the cell's ability to take up other amino acids, while glycine acts in the opposite direction;[18] glutamic acid also acts as a "cofactor" with ATP, probably sterically, in enabling the cell to take up potassium.[19] This steric function could account for the interference of synthetic (i.e., a mixture of levo and dextro forms) monosodium glutamate with brain development in rodents, and sometimes with nerve function in humans. Natural glutamic acid would be predicted by this theory to facilitate recovery of sensitivity in a depressed brain.

Lithium and rubidium have opposite influences on neuroexcitability, as predicted by this physical theory of the living state. Damadian[20] emphasizes the importance of this point, because "if one tries to explain these data in terms of conventional membrane pumps, one is at a complete loss to explain why lithium quiets the neuro-excitable state and rubidium enhances excitability."

The usual definition of a cell's "energy charge" is given in terms of ATP, ADP, and AMP,[21] with a high energy charge—an abundance of ATP—corresponding to what I am calling the resting state of "readiness." According to Szent-Gyorgyi[22] there is probably another sense in which cell proteins can be charged, namely, by addition to their "electron pool," which is a capacity of washed proteins to reduce large amounts of glutathione (discovered in 1925 by Hopkins; this capacity is what Racker has referred to in his cute phrase "nothing dehydrogenase"). Szent-Gyorgyi feels that this electron pool may provide the energy used to drive cell division. This energy seems to be derived mainly from glycolysis, which operates in the liquid phase of the cytoplasm. A related observation is that agents—e.g., estrogen—that promote mitosis also cause a proportionate increase in oxygen consumption and reducing capacity of whole tissue,[23] but that this capacity is lost if the cells are disrupted. This would suggest that the Hopkins electron pool is only a remnant of a larger and more delicately balanced pool, which can be kept in balance by draining electrons into oxygen as long as that is available; some pigments might serve as substitutes for oxygen in an emergency. Peroxidase and age pigment could catalyze this "draining" process.[23]

If such an electron pool is an integral part of the protein structure of the cell (Szent-Gyorgyi[22] has suggested the protein nitrogens as a likely site), then Szent-Gyorgyi's approach becomes a perfect complement to Ling's,[16] since the charge concentrations on the ion-binding sites of proteins are crucial factors in cell regulation in Ling's theory. It is well known that electron releasing or attracting groups have inductive effects through adjoining atoms, and Ling's view is that the strong ("cardinal") adsorbents can act through such inductive effects on adjoining charge concentrations. Szent-Gyorgyi also believes that these electrons could regulate the degree of protein hydration.[22]

The source of these electrons is likely to be NADH and/or NADPH, which are produced abundantly in the cytoplasm and which contain high-energy electrons (NADPH provides the energy for many biosynthetic reactions). For example, NADH and NADPH are the source of electrons for reducing glutathione, which in turn is in equilibrium with the SH groups of proteins.[23] Niacin is a component of these molecules that are so important in energy delivery. In a niacin-deficient animal, estrogen has no effect, so if estrogen is acting through its influence on the

electron pool, NADH and NADPH seem to be necessary for energizing that pool. Of course the biosynthetic function would also be damaged in a niacin deficiency.

The fact that large doses of niacin can often cure schizophrenia[24,25] suggests that in this disease the energy charge of neurons may be low. This would affect the ability of cells to retain certain ions and the known mineral changes that occur in schizophrenia[26] may be similar to those that appear in general stress reactions, though possibly with the brain being most affected. A low electron pool in schizophrenia might account for the claim that schizophrenics seldom develop cancer, since the cancer state, like other mitosis-favoring -states, presumably requires a very large or excessive electron pool. (The resistance of schizophrenics to virus infections, allergies, and histamine,[27] would suggest lower susceptibility to cancerization by viruses or irritation.) In the normal states, proteins would be "charged" only enough to function, bind water, etc., and then energy production would be limited. In a sense, the schizophrenic would be "too weak" even to produce cancer.

Szent-Gyorgyi[28] has shown that a given process can have opposite effects in different tissues, depending on whether that tissue is already above or below its maximum capacity to produce the particular effect. Recognizing that cells can have different degrees of structure according to their normal function and position in the developmental gradient, we should look for concepts that can combine generality with recognition of individuality, rather than grasping for undergeneralized answers such as "special receptor" theories.

Many people have suggested that pigments such as melanin may be able to function as electron acceptors, as an alternative to oxygen—no one has yet thought of a better explanation for the occurrence of pigments in the nervous system (e.g., the substantia nigra), in association with rapid mitosis,[29] e.g., melanoma and skin irritation, or in hormone imbalance or vitamin deficiency,[30] e.g., pellagra, Addison's disease, "melasma of pregnancy." We could imagine the pigment receiving electrons that "overflowed" from the electron pool, in case of a control error, or that leaked out of the pool, in case of structurally defective protein-gel systems. A phase shift of the cytoplasm toward "melting" would be the common event. Discontinuity of the proteins probably causes the low conductivity. The fact that abnormal pigmentation occurs in a niacin deficiency and in association with psychosis[31]

suggests that a metabolic or structural energy problem may be the key to both conditions. The observation that ascorbic acid with its high electron energy can be helpful in psychosis (Cott, ASA Publication) as well as in B-vitamin deficiencies has the same implication—ascorbic acid has both structural[30] and energetic effects. The electron donor potential of a substance has been successfully used to predict its effect as a hallucinogen,[32] and combinations of donor and acceptor substances induce muscle contraction[33] and may be involved in dyskinesias.[31]

Usually we think of both "error" and correction as being on the molecular level. However, control processes are likely to be of a physical nature first, followed by a chemical adaptive response. For example, if oxygen is physically restricted, the resulting lactic acid tends to restore the oxygen supply by causing vasodilation. Transmitter granules in nerve endings likewise are believed to be ruptured by physical changes in the cytoplasm, leading to the release of transmitter substances. Thus, we might look first for unusual functional states, such as stressed consumption of oxygen or glucose, or a nutritional block to such consumption, as provoking the release or synthesis of unusually high or low amounts of regulatory substances. Even vasodilators or vasoconstrjctors are ultimately regulators of the cytoplasmic "phase"; some hormones may do this more subtly, though. In this connection, it is interesting that a vasoconstrictor action has finally been demonstrated for LSD. The action of niacin as a vasodilator may be significant in its ability to block intoxication by hallucinogens (personal observation), as well as to block the symptoms of schizophrenia.

Schizophrenics typically have an abnormal serotonin concentration in their pineal gland. The pineal is rich in both serotonin and its N-acetylated, O-methy-lated derivative, melatonin, which has the function of concentrating melanin, making it seemingly disappear by withdrawing it from the extremities of the melanocytes. An interesting complexity is that the hormone is chemically closely related to the pigment that it regulates. The enzyme peroxidase, which is almost universally induced by irritation or stress, is involved in the synthesis of melanin.[31] The same enzyme can efficiently dispose of both electrons and oxygen.[23]

The pineal is closely associated with the optic thalamus and the reticular system, and is functionally involved in response to light, and is antagonistic to the gonads' production of sex hormones.[34] Its involvement in the visual system suggests it would be important in perception

and dreaming, and related to agents that either stimulate or suppress the dream-consciousness, such as LSD or alcohol.

A common item of folklore is that alcoholics are likely to be lightly pigmented people; sexual problems are often suggested, but usually are treated as an effect rather than a cause of alcoholism. Sensitivity and imaginativeness are frequently attributed to alcoholics. (Newsweek[35] reported successful use of lithium salts to treat alcoholism; this could be interpreted as acting to depress the "dream process," lowering excitability.)

Rat experiments[36,37] have shown that the pineal gland is involved in preference for ethanol: injected melatonin makes them prefer alcohol, as does keeping them in the dark. Removal of the pineal prevents this response to the dark.

It is well known that alcohol suppresses dreaming, usually for several days following intoxication, while the alcohol remains in the body. The body's "need to dream" is temporarily suppressed, but catches up later with a night or two of unusually intense dreaming. Continuous intoxication presumably builds up an increasing "dream pressure" that can eventually break through as waking dreams, or "delirium tremens." LSD works the other way, stimulating intense dreams even when awake, but causing a few dreamless nights when its direct effect wears off. (Para-chloro-phenylalanine, which blocks serotonin synthesis, not only interferes with sleep—especially R.E.M. sleep—but it causes rats to reject alcohol, and to become hypersexual[38]). The dream process involves greater conductivity through the head, whether it happens during sleep or when awake (my unpublished observations). This suggests that it corresponds to a high efficiency "resting" state.

It seems likely that human alcoholics, like the alcoholic rats, have excessive melatonin. This would account for the idea about their light pigmentation and possibly for an associated sex problem, since melatonin also suppresses the sex hormones.[34] Serotonin and reticular formation implants also have this suppressive action; male and female hormones may respond differently to serotonin and melatonin.[34]

Drinking would tend not only to suppress the dream consciousness (imagination may be a source of frustration), but may also antagonize the antigonadal action of the overactive pineal, though I don't know of any study that would indicate this—alcohol's occasional ability to increase sex hormone action is generally attributed to liver damage.

To the extent that psychosis is associated with excessive pigmentation, we might guess that it corresponds to a deficiency of melatonin; abnormal levels of serotonin (precursor of melatonin) in the pineals of schizophrenics could be interpreted in this way.

Stress, among its many effects, causes an increased synthesis of uric acid,[30] possibly as a useful adaptation, since uric acid levels correlate positively with mental activity and efficiency. However, uric acid can catalyze the oxidation of epinephrine,[31] and if this leads to elevated adrenochrome levels, it might interfere with cytoplasmic gel structure by acting on glutathione.[39]

Migrainoids typically have unusually vivid visual imagery and high electrical activity of the brain stem; a sudden drop in serotonin level is considered to be responsible for the swelling blood vessels that cause the pain, scotoma, etc. The travelling symptoms described by Reich and others may indicate that a certain mass of vessels exceeds the organism's vasoconstriction capacity; the demonstration that autonomic training can stop a migraine (by raising the temperature of the hands), the fact that sleep or orgasms can often end the symptoms, or that rectal stuffing can induce a headache, would be consistent with this idea. The "substitution" of bronchitis or piles (both involving vasodilation) for migraine would probably be conditioned by factors such as diet, activity, posture, etc. A high metabolic rate of any tissue will tend to cause reflexive vasodilation to maintain adequate blood circulation, as will relative starvation of the tissue, as in a riboflavin deficiency. In the migrainoid person, high brain activity, low blood sugar, and disturbed intestinal absorption may be interacting factors. Chernigovskii[40] has discussed some of the ways in which brain, blood sugar, and the intestine can interact.

The pituitary hormone, MSH (melano-phore-stimulating hormone), which causes darkening by dispersion of melanin, seems to act by way of interfering with glycolysis.[41,42] High pH and hypo-osmolarity[41] can also cause dispersion, which suggests that a phase transition (gel to sol) is involved. Kinosita[43] has reported exactly this gel-sol transition and has also demonstrated that the pigments seem to follow electrical gradients within the cell.

The idea of an altered state of the protein-water system makes it easier to see the darkening event, pigment dispersion, as a single process:

deficient melatonin, excess MSH, deficient niacin, or irritation, would all promote the low conductivity, low efficiency, anti-dreaming state.

During exhausting fevers and after drinking too much, I have experienced a defective kind of dream, a kind of analytical, verbal delirium, in which one word only leads to another word. In place of fluid and integrated imagery, there was just a kind of fizzly yellow, or swarming orange, activity. Mental satisfaction becomes impossible in that state. (Green and blue usually seem to be suppressed in that kind of state.)

Since I believe mental imagery is the real, working structure of language, I think a related kind of damage to the dream system, or dream metabolism, would account for the peculiar nature of "schizophrenic" verbalization. The damage would be both energetic and structural and would act by an effect on tissue conductivity. (An important difference between the cancer state,[6] and schizophrenia, on the cell level, would be that cancer depends on glycolysis, while glycolysis is specifically depressed in schizophrenia, according to this view.)

This theory, unlike others used as a basis for Orthomolecular psychiatry, offers a great range of substances that may be used simultaneously and possibly provides a better and more general basis for understanding synergisms (such as Ling's ATP-glutamate-potassium interaction). It specifically opposes the premature assumption that any particular metabolic error is genetic and proposes instead the investigation of environmental factors (including the uterine environment) that could alter the physical state of the cytoplasm. The observations of poor muscle tone in very young infants who later become schizophrenic has been used to argue for a purely genetic origin, but it could as well reflect a bad uterine environment, such as could be caused by an inadequate placenta.

Implied Theraputic Approaches

This biophysical theory argues that altered consciousness (and the behavior it produces) is a question of both bioenergetics and "biomicrostructure," and implies that a therapy should attempt to create the desirable state of structure and energy by intervention at crucial—and possibly numerous-points.

If it is possible to introduce ATP directly, its use would be suggested by the theory, since it is one of the central points in both energy

metabolism and structure. Creatine phosphate, which is in equilibrium with ATP, might be an alternative way of raising ATP concentration since it is at a higher energy level and would not introduce additional adenosine, thus allowing a higher ratio of ATP to AMP, if not an absolutely higher concentration of ATP. ATP has been found to improve the functional state of the brain (vestibular analyser) when used with Pyridoxine, increasing its stability and shortening postrotatory nystagmus[44] Also, ATP promotes healing of corneal wounds at high altitudes, when applied locally with 4-methyluracil.[45] Since ATP hydrolyzes rapidly in blood, it might achieve these effects partly through vasodilation. Recent in vitro studies show that ATP prevents leaking of enzymes and other proteins from cells (Science News, 1974).

Other "orthomolecules" besides niacin would, according to this view, include potassium, magnesium, vitamin E (improving oxygen supply, facilitating cell retention of proteins, and even, according to Matusis,[46] increasing ATP content), L-glutamic acid, inositol (stabilizer of cells and proteins against denaturing or "dehydrating" influences[47]), the other B vitamins, vitamin C, and anabolic steroids (e.g., testosterone, progesterone, ginseng, eleutherococcus) to promote protein synthesis and retention of potassium and creatine and ATP. Progesterone may be particularly important in female schizophrenics, since it commonly seems to promote emotional stability and even has an anesthetic function in large doses.[48]

Vitamins A, E, C, and B_2 either mimic or potentiate testosterone to some degree.[49] I am currently investigating the function of folic acid in allergic, immune, and perceptual processes.

The electronic aspect of the cell's energy charge suggests that cysteine or reduced glutathione might be desirable, especially if there is evidence that glutathione is being destroyed by something like adrenochrome. (Sulphydryl blocking can impair glycolysis, as can a niacin deficiency.) The theory of donor-acceptor interaction might eventually lead to a specific understanding of the "electronic leak" and how best to intervene, though it might not be such a discrete problem as some theorists have hoped.

The glutathione peroxidase which is released when mitochondria swell[50] might be involved in the "electron leak," and so things which cause uncoupling of oxidative phosphorylation and mitochondrial

swelling, such as unsaturated fatty acids[51] should probably be controlled in the diet.

Since the normal person has sharp diurnal cycles of brain activity (reflecting a proper concentration of the "brain" amines) and many psychotics have flattened cycles, involving disturbed sleep as well as disturbed waking consciousness, cyclic light stimulation of skin and head might be desirable to support regular cyclic activity of the pineal gland and brain. This would also tend to increase sex hormone production by the gonads.[34] The brain's "background activity" might have what in the heart is called the "staircase" effect, in which structural readiness seems to leak away if the tissue doesn't become active often enough—"function builds structure, and structure produces function."[22]

"Rhythmotherapy," the imposition of normal rhythms, is being done with the apparatus called "LIDA," which produces pulsed light, sound, and UHF currents, and a breeze on the face.[52]

Hyperbaric oxygen therapy has been used in relieving psychotic symptoms,[53] but this doesn't seem appropriate for creating lasting improvement. The opposite condition, i.e., high elevation, has caused lasting improvement in psychosis (Mir-rakhimov, 1972) and many somatic and psychosomatic conditions, and the mechanism (according to the animal studies of F. Meyersonet al., 1972) is the adaptively increased number and efficiency of mitochondria in the brain, resulting in improved learning ability. Also, MAO activity decreases at high elevation while respiratory effectiveness increases.[54]

In a pharmacological approach, reduced expenditure of glycogen, ATP, and creatine phosphate,[55] combined with increased protein synthesis[56] and increased resistance of cells and organisms to stress, can be achieved with ginseng, eleutherococcus, and 2-benzyl-benzimidazole,[57] used singly or in combination. Piracetam, an analog of GABA, improves learning, increases resistance to toxins or oxygen deprivation, and increases bilateral symmetry of function in the cerebral hemispheres.[58]

The importance of improving protein synthesis is implied by the observation that serum from schizophrenics inhibits protein synthesis in rat cerebral hemispheres, hypothalamus, and cerebellum.[59]

Several people[60] have suggested an identity of acetylcholine, epinephrine, and serotonin "receptors," and this structural-energetic theory similarly would suggest that "specific receptor" psychopharmaceutical approaches lack a proper physiological basis. But studies of

psychoactive agents can contribute to a general understanding of cell and brain function and can possibly support an Orthomolecular approach. For example, when excessive cholinergic activity is involved in nervous dysfunction (and excessive acetylcholine can block cholinergic synapses[61]), cholinolytic cell stabilizers (e.g., acetylcholine or tetramethylammonium with the adamantyl radical substituted for the N-methyl group[62]), might be used to stabilize nerve function while actual repair processes occur under Orthomolecular therapy. The adamantyl radical is also useful in treatment of Parkinsonism and viral infections[63] again suggesting a general biophysical structuring effect, as in cholinolytic processes. The "Pavlovian dose" of caffeine which produces sedation is very small and probably acts by increasing the degree of structuring of cells; larger doses, which would promote an "adrenergic" state, might intensify the symptoms of schizophrenia or alcoholism. The cholinergic and muscarinic drugs (e.g., prostigmine) might shift the nervous balance in the right direction if the cholinergic synapses aren't blocked by excess acetylcholine.

The Russians have two electronic techniques that may serve as alternatives to ECT and which may in fact give some insight into the effects of ECT on the brain. Electrosleep (produced by 5 Hz to 100 Hz pulses, with peak current of 5 mA to 8 mA applied to the eyes—negative pole—and mastoid process—positive pole) has been used in treating "functional disorders of the CNS," autonomic and endocrine functional disorders, etc.[64] High frequency (5000 Hz to 6000 Hz) currents have been found to stimulate the brain.[65]

In embryonic muscle cells, when the "depolarizing fast acetylcholine receptors" are blocked by snake venom, then the cell's "slow polarizing acetylcholine receptors" are revealed[66] This type of receptor may be responsible for the "trophic" influences which maintain high polarization and which seem to be involved in such things as the "Bowditch staircase." Electrical stimulation may act on similar "receptors" in neurons.

Vitamin B_6 is a coenzyme in carboxyl-ation reactions and as such is involved in the synthesis of serotonin from 5-hy-droxy-tryptophan, and also in the formation of GABA (gamma-aminobutyric acid) from glutamic acid. In the "resting" state, cell water seems to be more orderly, as if it had a lower "structural temperature." Some enzymes are inactivated by cold and presumably would be inactive in the resting state. GAD (glutamic acid decarboxylase) has been found to be among these peculiar

enzymes, and this is the enzyme which decarboxylates glutamic acid, producing GABA. GABA has been shown to be a mediator of nervous inhibition on the basis of several criteria, including heightened GABA liberation in sleep and near-sleep.[67]

This would seem appropriate if the physical state of cell water is participating in brain regulation. During brain "activation" or exhaustion, this enzyme should become more active, producing more GABA and presumably thereby promoting rest and restoration. Since hydroxylamine is an inhibitor of GABA degradation, it would be interesting to see what effect it has on psychoses, though it may be too toxic to be practical; the same might apply to hydrazine, which is used with considerable success in inoperable cancer and often induces sleep as well as preventing cachexia. It raises the level of ATP systemic ally. Injected GABA is usually considered to enter only the fetal or infant brain, because of the "blood brain barrier" of the more mature organism. However, Nasonov and his students have shown that many kinds of stress will eliminate the barrier and that it can be interpreted as a physical state of the neuron, governing solubility. This suggests that GABA itself may be able to enter the brain and exert a beneficial inhibitory action if the brain is in a state of exhaustion from stress.

Another enzyme that should be investigated from this point of view is NADase, since it too shows what may be a sensitivity to structure: in cell homoge-nates, it is sufficiently active to destroy NAD and thus stop glycolysis at the triose phosphate stage;[29] it is inhibited by nicotinamide, but is also relatively inactive in the intact brain, at least in the intact non-schizophrenic brain.

Magnetic fields presumably act biologically by acting on the structure of water, and Kholodov has established that a continuous sinusoidal magnetic field has a sedative and inhibiting effect, modifying the EEC and raising the level of GABA in the brain.[68] The activity of oxygen increases in magnetically treated water,[68] so there might be a direct effect on energy production.

Since DMSO has been used successfully for treating mental retardation, with removal of cataracts as a side effect, its effect of "structuring" water, or lowering its "activity" according to a Soviet study, and of promoting oxidation of glucose by quinone (my unpublished observation) suggests that it might improve the function of nerves and other cells by promoting the desired high energy state.

During an epileptic seizure, a localized vascular "blanching" has been observed in the exposed brain. Since vasoconstriction occurs in the brain when the concentration of carbon dioxide is low, such a spasm might occur when metabolic inefficiency interferes with the production of carbon dioxide. Thus epilepsy and schizophrenia might benefit from similar treatments. This theory suggests that we should look for more general mechanisms in known therapies: for example, the ability of Dilantin to lower insulin levels could improve the supply of glucose to the brain.

One of the older therapeutic uses of niacin is in the treatment of "trench mouth," which is a reaction to stress,[69] though a protein deficiency is also probably involved. Since the gums are responsive to many agents (including Dilantin and cigarette smoking) and are easy to inspect, they may provide an additional means for following the course of recovery when schizophrenia is being treated with niacin.

A Holistic Physiology of Memory

Multidisciplinary Research, Volume 3, Number 2, 1975

WHEN we think of memory, it is customary to use concepts such as "storage," "reservoir," and "trace," and to look for ways in which the "trace" might be integrated with "sensory input" and "motor output." I want to suggest that these concepts are derived from a particular philosophical approach which is deeply embedded in "western civilization," but which is probably not able to deal appropriately with questions such as consciousness, memory, and organism.

Abundant experimental evidence has shown that perception is an active process. Yet nearly everyone seems satisfied to diagram "sensory input" and "motor output." Where is the sensory output in the typical diagram of a functioning organism? It is forgotten, generally, because the passive reservoir of memory can do nothing but receive sensations and store them until they are drawn upon for motor activity. But what could sensory output consist of? How could consciousness go out? This odd question is normally avoided by avoiding the discussion of consciousness—it is said to be beyond the scope of science, etc., while "input, storage, output" are simple, manageable concepts. Those concepts are useful in the analysis of a typewriter, but a typewriter doesn't have a fundamental selectivity of the messages it receives. Since perception is an active process, it is necessary to consider sensory output, or how consciousness "goes out." This is not mere muscular orientation, and it involves many distinguishable levels: thresholds are adjusted, patterns are sensitized, and the whole perceived world-space is finely adjusted to the flow of perceptions.

There have been various demonstrations of structured, meaningful antidromic impulses on the optic nerve. This is an output through a sensory channel, and it powerfully determines perception. Passive movement of the eyeball creates the illusion that the visual field is moving, while an intentional movement of the eye or head involves a coordinated movement of the perceived model of space. This perceived model of space, and its ability to jump in synchrony with expected changes of perception, is another aspect of the active consciousness. It is this active model of the world which Anokhin called the "acceptor of action." Once we recognize this active perceptual model, we commit ourselves

to Anokhin's "completion of the reflex arc," the feedback principle in which motor activity is inseparable from "image," "sense," intention, and consciousness.

At first, the imbalance between many sensory nerves to the brain and few motor nerves from it suggests that we sense more than we can do, but there is normally not any problem with refining muscular activity to suit the situation. It is the sensory "output" system which provides the means of orientation and control. This is equivalent to the view of Pavlov's followers that the cortex is a "sensory" system, even when it is regulating the musculature.

It has been suggested that the position of the eyeball is perceived largely by an awareness of the impulses that are being directed to the eye muscles. If this is true, it is only a "simplified" case of what Anokhin presents as the general nature of organismic control. The two elements, active perception and perception (feedback) of movement, constitute a picture of the active consciousness, of the active organism. The imaging cortex fits the organism to the environment, both perceptually and motorically.

At the Seventh World Congress of Cardiology (Buenos Aires, September, 1974), there were about a dozen reports by Western scientists relating to the role of nerves in heart disease, but previously this factor was considered important only by the Russian Pavlovians. Pavlov developed the concept of cortical control of trophic processes in all tissues, although the study of nerve trophism was already established in Russia in the mid-nineteenth century. Bykov (1957), Palladin (1959), and Filatov (1957) are among those who have studied the influence of the cerebral cortex on tissue biochemistry. Nerves also have trophic influences on other nerves. Nerve trophic influences are coming to be accepted by Western physiologists (e.g. Brown, 1974). There is probably no consciousness without a body component, a feeling tone, an orientation, a trophic influence.

In this context, it is interesting to remember the old physiological demonstration of the mammalian "nerve net," in which the anal sphincter of an anesthetized cat is attached to a recorder—students are invited to think of a stimulus, such as tickling the ear, to show that every stimulation will modify the tone of the muscle.

Our perceptions are modified by the tone and balance of our autonomic nervous system. Certain gestures and postures modify our

perceptions and recollections. Lying down goes with a certain style of thinking, standing, with another style. Some personality types move their eyes to the left while thinking, others to the right; blinking and rolling the eyes seems to facilitate another kind of mental process. Blinking is commonly used to "erase" eidetic images. These physiological events are closely related to our "getting a perspective."

Wilder Penfield found that electrical stimulation could promote recall. The memories could be repeatedly recalled with repeated stimulation of the same point. Pavlov spoke of a focus of learning, and the Russian concept of a dominant is also thought of as a centering in the brain. The holographic idea of brain function also implies the importance of "perspective." I think we can work from the organismic nature of this perspective, or "field," or orientation, down to the cellular and chemical level, but it would be very hard to go in the opposite direction.

When we talk about perspectives, we aren't making a distinction between perceiving and remembering. Similarly, learning and perceiving can both be thought of as active, constructive processes. Of course, perceiving something familiar is not the same as perceiving something new, which requires learning or discovery. The difference can be seen in terms of the idea of development, in the biological sense. Growth, differentiation, and integration are included in this concept. There is also an implication of evolution and generalization. The idea of "storage" can be fully replaced by this more phenomenological, experiential, empirical idea.

A common implication of the idea of "storage" is that memories must be inert while in storage; the organismic approach suggests that various degrees of integration can exist. Some of the organism's developmental processes may reach dead ends, become isolated, irrelevant and inert. But if the organism is making use of most of its experiences, there will be fewer dead ends. Once entering this complex world of interlocking meanings, we can't leave it without undergoing something like a developmental regression. And to the extent that it is present, the question of "recall" disappears or at least changes its form.

If we consider some of the recent historical reasons for requiring the ideas of recall, storage, and retrieval, it might give us some suggestions for studying the holistic aspect of memory.

A few years ago, it was common for psychologists to claim that there was a tremendous "information reduction" in visual perception, because, for example, only about six simultaneously presented points seemed to be the maximum that could be recognized instantaneously. The existence of eidetic imagery has always made this a foolish position, but it was only recently that many behaviorists were made to recognize this by studies of people with eidetic imagery, using computer generated images composed of millions of random dots. Holding as they did, the dogma of "tiny input, tiny output," they were forced by the fact that many people know many things, to conclude that the tiny stream of input was stored in a fairly large black box.

Now we just can't avoid knowing that the channel of visual perception is very large: ordinary people can, for example, recognize at a glance which photographs in a series of 2000 are repeated. We also have to grant that perception is active: the perceiver brings himself and his world to bear on the thing perceived. The "very large input channel," therefore, is made even larger by the activity which recognizes, which "intends," which gives meaning. In a normal continuing situation, this amplification by recognition is momentary and continuous; in a typical, sporadic experimental arrangement it may almost disappear, or appear later so that it appears to be something separate. When we see that perception is rich and active, and constitutes the phenomenological or empirical being of the organism, we aren't forced to ask where something is "stored" when it isn't explicitly present. That question, "where is memory stored?," is somewhat like the question, "where is the organism stored when it is quick-frozen?" In fact, at that time, the organism exists only potentially, since its future functioning depends on the circumstance of successful thawing, which is a reconstruction of the physiology. Another example: when an organism is eating, where is its mating behavior? Is it in storage? Only in the sense that the organism developed its sexual organs, its nervous system, etc. at some earlier time—and eating is, in fact, a necessary preparation for mating and other behavior. Recognizing the full nature of the organism, we can say that one behavior is explicit, while others are implicit.

A child develops its sexuality, its style of movement, its language, its visceral peculiarities, its skills, its image habits, and other ways of dealing with the world. If it is idle to talk about our "sexual reservoir"

which "stores mating" while we read or eat, then it is idle to talk about a reservoir of words or images.

Many geneticists are talking about manipulating, transferring, and storing DNA, and the assertion is commonly made that the DNA contains "all the information in the organism." It has been known for decades that cleavage patterns, which determine important biological traits such as which phylum the organism belongs to, are governed by the cytoplasm independently of the transplanted nucleus. Many other experiments show inheritance of structural properties of the cytoplasm, without involvement of "genes." So it is false to assert that DNA contains all the information needed to make an organism. Unfortunately, this mistaken genetic thinking is taken as a paradigm by many of the people who are thinking about memory molecules and information storage. The "reservoir" tends to be equated with molecules which are known to transfer learned behavior. There are probably many factors which could transfer learned behavior. The quick decay of the transferred learning suggests that the transferred molecules are not all that is necessary to establish or integrate that behavior. But even if a perfect chemical transfer method is achieved, it won't be an argument for the existence of a storage system distinct from the input system. To use an analogy, we could imagine that technicians could eventually restructure the cytoplasm of a flatworm egg into the cytoplasm of a snail egg, by transferring essential parts of the snail egg and placing them appropriately. In this case, we see that being and functioning are equivalent, and nothing is gained by talking about storage of the snail egg's function.

I think that by criticizing some of the empty and misleading formalisms in this way, we can clear the way for a better understanding of the real physiology of memory, of memory transfer, and of brain function in general.

A New Approach to Detoxifying

Townsend Letter for Doctors, January, 1989

Ernest Krebs, the inventor of the laetrile cancer treatment, compiled some interesting facts about cancer metabolism. Noting that cancer cells are typically fairly deficient in the enzyme rhodanese, which protects cells against cyanide poisoning if the dose isn't too high, he theorized that cyanide might selectively kill the relatively unprotected cancer cells, especially if the dose could be concentrated near the cancer.[1]

While amygdalin releases a large proportion of its cyanide in the bowel, his original laetrile, the glucuronide form, should liberate its cyanide largely in areas of inflammation or injury, including cancers.

Although cancer cells have a low level of rhodanese, they typically have intense glycolytic metabolism which compensates for their respiratory defect. Otto Warburg and Dean Burk showed pretty decisively that "defective respiration" exists in all of the cancers studied.

Maybe we can see a different meaning in the same facts.

What if the respiratory defect that was so carefully documented by Warburg and Burk is the result of damage to the detoxifying rhodanese enzyme? If cyanide is a general threat to respiration, a deficiency of rhodanese would allow it to damage respiration, and this, according to Warburg, should lead either to cell death or, if the cell can adapt adequately, to the production of cancer.

Rhodanese occurs in all animals, and seems to be localized inside the mitochondria. Although it does handle some other sulfur reactions, its basic function is thought to be the elimination of cyanide, by the addition of sulfur, forming thiocyanate. Thiocyanate is fairly non-toxic, though it can be broken down into cyanide again, and it does have a significant anti-thyroid effect.

Herbivores eat many plants that are rich in cyanide-releasing compounds, so it is logical that they should be equipped with rhodanese. But carnivores are not exposed to these toxic vegetable products, so it is hard to explain why they have the enzyme. The fact that serum albumin, which has many detoxifying functions, carries sulfane sulfur, the form which is used by rhodanese to react with cyanide, supports the idea that rhodanese is involved in the elimination of cyanide.

People who smoke or eat significant amounts of plant material are exposed to cyanide, but the fact that the rhodanese enzyme exists in all animals, whether their diet includes "cyanophoric" compounds or not, suggests that we might want to consider other possible sources of cyanide.

People studying lipid peroxidation in liver cell extracts noticed that carbon monoxide was being produced. Many people have observed that stressed cells emit ammonia.[2] There are industrial processes which use ammonia and carbon monoxide to produce cyanide, using a metal as catalyst.[3–5] Since carbon monoxide binds to metal atoms, it might be held in a form which reacts easily with ammonia. Then during stress, which causes both lipid peroxidation and ammonia formation, rhodanese would be needed to protect the respiratory cytochromes from the cyanide, which would otherwise inhibit respiratory energy production, and other processes involving the cytochromes. Within the mitochondria, a cytochrome P-450 converts cholesterol to pregnenolone. The loss of both energy and steroid hormones would have major consequences. Outside the mitochondria, many other cytochrome functions will be inhibited; other types of enzymes would also be inhibited.

Another possible source of cyanide would be bacteria in the intestine; methane and ammonia are other possible starting materials for making cyanide. The urea cycle itself, inside the mitochondria, is a conceivable source.

Even if dietary plant material turns out to be the main source of cyanide, it is important to be able to eliminate it efficiently.

When flowers of sulfur is taken orally, some of it becomes available for use in the rhodanese system. It might be less irritating and more effective to use a form of sulfur which is chemically more available, namely thiosulfate. (My thoughts on light removing carbon monoxide from cytochromes led me to think about photography; sodium thiosulfate is used to clear the photographic emulsion, removing the silver which was not exposed to light. In that sense, its activity as a reductant is equivalent to light's action).

In acute cyanide poisoning, a large dose of sodium thiosulfate (12 g) is injected rapidly; it is poorly absorbed when taken orally. I decided to try small oral doses, about 50 mg. a few times per day. It has improved my tolerance for chocolate and wheat, which I still reacted to in spite of using pregnenolone, which was permitting me to eat many other foods

that earlier would have caused migraines and asthma. Pregnenolone seems to stabilize the cytochromes physically, while rhodanese (with sulfur) restores their chemical activity. Some druggists still sell sodium thiosulfate as a treatment for skin diseases. It has been used to treat arthritis, which would be logical if it is able to increase formation of pregnenolone and the various steroid hormones.

Since very high levels of cortisone destroy the detoxifying cytochrome enzymes,[6] the use of thiosulfate—to restore any of the remaining cytochromes which might be blocked by cyanide—would seem to be appropriate as part of an anti-stress approach to disease. As far as I know, it hasn't been tried as part of cancer therapy; improving a cancer cell's viability might, as many people believe, reduce its virulence, but it might just make it a more energetic cancer cell.

A Physiological Approach to Ovarian Cancer

EnCognitive, January, 2010

SEVERAL years ago, George Crile, of the Cleveland Clinic, observed that his clinic had removed only 11 thyroids that year, and that they had done more than 5000 thyroidectomies annually in the 1920s. The reason for the change was that they found that there was rarely any reason to remove the gland; even thyroid cancers of most types could be controlled safely by using a thyroid supplement, to reduce the growth-stimulating action of the pituitary hormone.

Since many physicians still believe that destruction of the thyroid gland, by radiation or surgery, is an appropriate treatment for thyroid disease, it isn't surprising that there is so little attention given to the possibility of physiologically controlling the more aggressive ovarian cancers. The recent report that ovarian cancer is more common among women who have taken gonadotrophins, to promote fertility, will probably bring increasing attention to the physiology of ovarian tumors.

Around menopause, the pituitary gonadotrophins increase. Menopausal estrogen treatment shouldn't be called "estrogen replacement therapy," because the amount given is typically about 15 times higher than occurs in younger women. The reason for the use of such high doses is that the dose is increased until the pituitary gonadotrophins are suppressed. The reason for the menopausal increase in pituitary hormones is that the nerve cells which regulate their secretion have been killed or desensitized by their past exposure to estrogen; it is their reduced sensitivity that requires the very large doses of estrogen to suppress secretion of the gonadotrophic hormones.

Clonidine (normally used for high blood pressure) can be used as a skin patch, to control menopausal flushing; progesterone and DHEA prevent osteoporosis. After those issues have been taken care of, the question of pituitary hyperfunction should be considered, in relation to preventing ovarian cancer. (Combinations of safe substances including progesterone and naloxone can probably be worked out empirically.) A variety of other possibilities exist, including Gonadotrophin Inhibiting Substance, and antagonists to the specific gonadotrophin release hormones. Normalizing the menopausal gonadotrophins would have far-reaching effects, possibly improving the immune response.[1]

For years, it has been known that nuns have a high incidence of ovarian, breast, and endometrial cancer. Women who have children, or who take oral contraceptives that might suppress ovulation, are believed to have a lower incidence of ovarian cancer because of reduced exposure to the gonadotrophins. (Though cancers of liver, breast, and other organs are reported to be more frequent among pill users; prolactinomas seemed to become epidemic after the pill was introduced.)

Normal factors in the physiological control of the ovaries include an interaction between the thyroid and the gonadotrophins; the combination of hypothyroidism and stimulation by gonadotrophins can cause ovarian cysts to develop. Small amounts of estrogen can increase both FSH and LH, and large amounts of progesterone decrease both FSH and LH.[2]

If ovaries are removed from their normal location, and transplanted into the spleen, so that their secretions go directly to the liver where they are inactivated, they produce tumors because they are subject to "hypersecretion of gonadotrophic hormones."[3–5] Other experiments support the idea that ovarian tumors develop from excess pituitary stimulation. For example, removal of one ovary was essential to produce a tumor in the other ovary even after it had been irradiated.[6] Similarly, no tumors developed in irradiated ovaries transplanted into other mice, irradiated or not, as long as they had their own ovaries, which kept the pituitary functioning normally.[7]

Progesterone and estrogen "receptors" can be demonstrated in some ovarian tumors, and by analogy with breast and uterine tissue, in which progesterone generally retards cell division and estrogen stimulates it, hormones have been investigated as possible therapies for ovarian cancer. Although *in vitro* studies show that there might be a direct action on the tumor cells,[8] the reports of positive responses in patients treated with progesterone or synthetic progestins[9–11] are more interesting, since the most logical approach involves normalization of the pituitary gonadotrophins.

If it is true that a "deficiency" of the so-called "essential" fatty acids suppresses gonadotrophin secretion,[12] then a diet lacking those estrogen-promoting[13] substances should be both protective and therapeutic for ovarian cancer (assuming that the results seen with progestin therapy are produced by gonadotrophin inhibition.) If our purpose is to delay the menopausal rise of the gonadotrophins, then it is interesting that

lipid peroxidation of polyunsaturated fatty acids (which increases with age) can be intimately involved in loss of progesterone forming ability by human steroidogenic tissues.[14] That is, aging decreases the ability of certain brain cells to inhibit the pituitary gonadotrophins, and it also tends to decrease the steroidogenic tissues' ability to produce the regulatory steroids.

After menopause, estrogen is produced less by the ovary than by other tissues, including fat cells. Breast cancer cells can produce their own estrogen. This means that estrogen is one of the "cancer hormones" which, secreted by the tumor, promotes the growth of the tumor and also has a systemic pro-cancer action. Ovarian tumors, too, can cause great systemic hormonal imbalances, which should be investigated routinely in a physiological approach to the disease. After menopause, estrogen is largely produced by conversion of "androgenic" steroids from the adrenal glands. It would be desirable to be able to inhibit the conversion of the adrenal steroid precursor to estrogen. Newton, et al.[15] showed that progesterone inhibits the conversion of the precursor to estrogen, and P.K. Siiteri showed a similar effect for thyroid hormone.

A diet low in polyunsaturated fats facilitates thyroid hormone secretion, transport, and tissue response to it, and would minimize the stress-related or age-related inhibition of progesterone formation by lipid peroxidation. Vitamin E and vitamin A also protect against lipid peroxidation, and vitamin A is specifically involved in progesterone synthesis. Vitamin A also has a variety of anti-estrogen functions,[16] that are often considered to be relevant to protection against cancer.[17–19]

All of these dietary and hormonal approaches to normalizing the pituitary gonadotrophins and controlling ovarian cell division are things which also tend to optimize the immune response. A slight deficiency of iron is probably protective against cancer, since there are several ways that iron can promote cancer, apart from its role in damage to the immune system and the steroidogenic system by lipid peroxidation.[20,21]

A Revolution in Physics

Multidisciplinary Research, Volume 4, Number 37, 1976

NIKOLA Tesla was aware that the earth has a high negative electric charge; he felt that going to high mountains, where the charge tends to be more concentrated, stimulated him mentally. It is now generally believed that the sun, too, has an excess of electrons. (H. C. Dudley demonstrated that the earth's charge could be used to make small rockets reach much higher altitudes.)

In spite of experimental evidence, this "electronic background" was conceptually hard to accept—some people still prefer to think that the observable charge gradient results from a source of positivity in the high atmosphere.

Electrons are relatively easy things to grasp, in a technical sense and in an intellectual sense—they have a high charge in relation to mass, and so flow easily, and are very useful. Nevertheless, the idea of a charged earth was hard to accept.

If there were uncharged electrons, they could be even more abundant, yet harder to detect. It has been proposed (Dudley, 1963, 1972) that there are several types of uncharged particles, including "neutral electrons," forming a "neutrino sea." The neutrino was not notoriously hard to detect, even when it was necessary to assume its existence to account for the recoil energy of a decaying atom.

In this century, two major ideas have been ruled out as general interpretive frameworks in physics: mechanistic or deterministic causality, an ether which serves as a medium for propagation of electromagnetic radiation.

DeBroglie (1959), Bohm (1959), and Dudley (1971) are among those who have more recently proposed a need for a "sub-quantic" medium. Dudley has elaborated the assumption that the medium is a "neutrino sea," with great success.

He was able to use it to account for the Fitzgerald-Lorents contraction. It is interesting that the Fitzgerald-Lorentz idea was first introduced to justify keeping the ether theory.

He predicted (Sept., 1972) results like Anderson's discovery of anomalous nuclear decay rates (Nov., 1972) when he postulated that

> *populations of nuclei which are now considered to exhibit spontaneous decay at a constant logarithmic rate, consist of units each of which is a linear resonant system. Parametric excitation of such a unit by an energy input at some critical level or rate may cause the system to react... ...with such a model there would be no necessity of assuming acausality in describing the "decay" of nuclei or particles.*
>
> *Dudley has warned that these new ideas regarding nuclear stability, if true, will invalidate the present AEC beliefs about reactor safety, etc.*

My involvement in this subject relates mainly to my view that biological processes are largely governed by crystal-like states of tissue water. Because of my familiarity with Polanyi's book, Personal Knowledge, I considered the applicability of his adsorption isotherm (1914) to biological ordering processes. Among other ideas I was considering as a possible guide to ordering processes was N. A. Kozyrev's proposal (about 1965) that time, which he had been viewing as a cosmic source of meg-entropy (lunar vulcanism, 1959; planetary asymmetry, 1964) might in some way be utilized by organismic forms. It was only recently that I read Polanyi's later (1920–25) scientific work on crystals and chemical reaction energy, and realized that his scientific work had been guided by a holistic principle, just has his more recent philosophical thinking is. As I presently understand it, his "mechanism for holism" was very similar to the "energy source and sink" that Dudley understands to be a neutrino sea.

A 1971 newspaper report about Anderson's experiments with monomolecular layers of radioactive chemicals aroused my interest in the likelihood of "new" kinds of surface, crystalling, and adsorptive forces or processes.

In Personal Knowledge, Polanyi had told the story of conflicting interpretations of the Michelson-Morley experiment. When Dror Sadeh's experiments were reported, showing, for example, a "red-shift" between locations on the east coast of the U.S., it seemed pretty obvious that either "time" (cesium clocks) or radiation (radio waves and light from stars) behaved in ways not acceptable to conventional theories.

When I heard of Dudley's objection to the Rafele-Keating experiment (which was claimed to verify the clock paradox of relativity), and to other

current dogmas, I asked him about the possible relation of crystals to the neutrino sea, and he indicated that he had predicted their interaction with phonons and rotons in crystals. This is where a "physical" theory becomes obviously relevant to organisms and their highly ordered water structures.

Dror Sadeh's clock seemed to slow down following sunrise and moonrise. Frank Brown had earlier found that hermetically sealed potatoes and oysters showed metabolic changes at sunrise and moonrise. Several Soviet biologists have argued that some kind of "radiation" other than electromagnetic is necessary to explain such biological sensitivity. A "sub-quantic medium," influences by events in the solar system, would be a conceivable explanation.

Bandyopadhyay and Chaudhuri have shown how the neutrino sea can account for gravitational attraction:

> *A body falls toward the earth because the charged particles of which the body is composed tend to move into a region where the dielectric constant is greater. Thus an electromagnetic interpretation of gravitation is obtained (1971).*

Bandyopadhyay and Chaudhuri also observe that "the variation of the neutrino energy density can be related with the evolution of the universe," though such variation is not an essential feature of their (1971) theory. They cite Dicke's (1957) observation that the red-shift (that is conventionally interpreted as a Doppler shift connected with the speed of receding stars) can be interpreted in a different way: if neutrino density changes with time, the dielectric constant of space changes, and atomic diameters and frequencies change.

Kozyrev's basic assumption is that time is a source of neg-entropy. He claims that "events," causal sequences, set through "time" to modify other events is the vicinity (1968). His language, and his observations, seem easier to understand if we imagine time as being at least partly a a tendency to increase (by consumption of gamma rays and neutrons, and production of hydrogen and neutrinos?), and the ability to act as an "energy source and sink" for a great diversity of physical processes, but with a single directionality or bias.

Thus, Kozyrev's suggestion about time influencing organisms, and his cosmology both overlap with the idea of an ether constituted by

a sea of neutrinos. Another similarity is their rejection of the basic assumption of randomness. It was Einstein's similar desire for a world without a "God who plays dice" that eventually isolated him from most contemporary physicists.

The idea of a sub-quantic medium not only offers a very coherent set of physical explanations, but it provides a very different kind of intellectual world and, more important, it restores objectivity to science, against the neo-Kantian view of orthodox physicists (such as Max Born), and of establishment intellectuals in biology (Monod), linguistics (Chomsky), sociology and anthropology (the structuralists).

The assumption of randomness wherever possible (electrons, nuclear decay, gene mutations, etc.), and the positivistic denial of causality, require a "mathematized" view of reality, which substitutes a very neat and clean knowing for a hopelessly messy and really unknowable material reality. Omitting those very gross assumptions, in favor of a neutrino medium, gives us a material reality which is completely knowable and lawful. Einstein considered the objectivity of reality to be of fundamental importance, but his attempts to achieve a theoretical description of such lawfulness were always within the formalistic tradition, and he considered progress in physical theory to be step by step removing attributes from the "ether."

Neo-Kantianism was flourishing in Germany at the beginning of this century (e.g., Hermann Cohen and Ernst Cassirer). Undoubtedly, this formalistic milieu encouraged the development of physics along similar lines.

By the 1930's, this style of thinking was being explicitly offered as a popular refutation of Marxism. In sociology these ideas have become strong defenses of the status quo: change has been defined as dysfunction. A biologist, Gunther Stent, has recently (1972) tried to give canonical knowledge (narrowmindedness) a biological justification. Many neo-Kantians offer the abstract, non-objective nature of modern physics as support for their view, and the physicists reciprocate by accepting their theory of knowledge in evaluating physical theories.

I view the revolution in physics that is under way as part of a broader cultural liberation.

In biology, it will be a basis for a new beginning.

Many high technologies may result from this new way of thinking. For example, if it turns out that crystals or other states of matter can be

used to coordinate or "pump" neutrinos—and this does seem likely from Dudley's and Anderson's work—it might be possible to achieve nuclear fusion at very low temperatures. (One of the diaproofs of Miller's positive results with his refined Michelson-Morley experimental set-up was a device that used helium gas for the light pathway. This particular "null" result, if Miller's 1000s of experiments are to be accepted as evidence for an ether drift, might have resulted from an ability of helium—a light and symmetrical atom—to resonate with the neutrino sea in a way that would locally adjust the drift to zero velocity.)

Normal science prefers heavy regularities to a tenuous completeness. It is still easy to laugh at the "ether" people, but only if the physicist doesn't read and remember much experimental physics. The "anomalies" are starting to seem more orderly than the "normal" physics.

The ideas mentioned here are intended as a sketch of the possibilities of the neutrino approach—what I want to emphasize is that many things, such as the red shift, that had been treated as answers, should now be seen as problems, still to be solved. If neutrinos offer better possibilities for getting good solutions to any problem, we should proceed to work out all the implications. It is at least certain that nothing can look the same to us once we have considered the possibility of matter and energy interacting with pervasive neutrino fields.

AIDS/Syphilis Treatments & Ideas

Townsend Letter for Doctors, June, 1988

Two of the best articles on AIDS that I have read are by Katie Leishman in *The Atlantic*.[1,2] In the earlier article, she discussed some of the poorly publicized alternative theories about the cause of the disease, and presented some of the arguments about the method of transmission, especially about lice. In the January article, she concentrates on the association between AIDS and syphilis.

Leishman quotes the argument of Jean McKenna, of Berkeley, that the AIDS-associated virus, HIV, is a by-product of the disease, rather than its cause, and that it probably only infects someone who is already immunosuppressed. Reading the older scientific literature, McKenna learned that both Kaposi's sarcoma and pneumocystis carinii pneumonia had been associated with syphilis.

The literature suggested that syphilitic patients are prone to various opportunistic infections, as AIDS patients are, although syphilis does not appear to suppress the immune system until its latent and tertiary stages. She tested twenty-four HIV-positive subjects (most of whom were ARC and AIDS patients) with a documented history of syphilis.

Although all of their FTA (fluorescent treponemal antibody) tests should have been reactive, twenty-one were not. McKenna speculated that all AIDS patients might have syphilis.

In 1981, before AIDS had been recognized, two German physicians, K. Dierig and U. Walthaler, guessed that gonorrheal endocarditis might be causing a patient's hot flashes, drastic weight loss, shortness of breath, and confusion, so they treated him with 40 million units of penicillin intravenously each day for three weeks. His symptoms disappeared, and later they found he tested positive for HIV, and a review of his 1981 laboratory tests "showed abnormalities consistent with AIDS." Dierig and Walthaler then used the same penicillin treatment on six other ARC and AIDS patients. All seven are now "clinically asymptomatic." (The usual treatment for syphilis in the U.S. is a single injection of 2.4 million units of benzathine penicillin. This form of penicillin does not penetrate the brain. In some countries, syphilis is treated for a year.)

Leishman also describes the work of Salvatore Catapano, of Valley Stream, Long Island. Thirty years ago, Catapano learned that the En-

terobacteriaceae stimulate immunity, and found that typhoid vaccine could stop the growth of tumors. When he saw patients with Kaposi's sarcoma, he was reminded of syphilitic sores he had seen in the tropics. Catapano believes that the tropical spirochetal disease, yaws, shouldn't be considered as a distinct disease. He advocates the use of typhoid vaccine to stimulate the immune system before treating AIDS patients with penicillin. Catapano also believes that "syphilis" infections can occur without the presence of a spirochete, possibly by a virus-like variant of the organism. This idea has been proposed many times.[3]

A few months ago, D. J. Bauer of Wellcome Laboratories, wrote an article on the history of antiviral drugs. I know of his 1959 work, in which he showed that copper inhibited the growth of a lipid-coated virus in the brains of mice, so I was surprised to see that he didn't mention copper or zinc, and that his story began with the introduction of amantadine in 1964 to treat influenza (which, like herpes and HIV, is also lipid-coated). I had been interested in amantadine for a long time, because it modifies nerve function in a way (anti-cholinergic) that I think mimics certain steroid hormones which I consider to be part of our natural antiviral defense system. So I was also surprised to see that Bauer gave no explanation of the origin of amantadine.

Amantadine (or adamantaneamine) is a water soluble form (1-amino-adamantane) of a substance that occurs in petroleum. I noticed that adamantane smells like camphor, and that it has a cage-like shape which is very much like that of camphor. Camphor has a long history of use as a germ-killer (e.g., Campho-phenique, for herpes), and was used successfully in the great influenza epidemic 70 years ago. I assume that the idea of using amantadine to treat influenza was based on its obvious similarity to natural camphor. An oxidized form of camphor, camphoric acid, also has a faint odor of camphor, and has been used as an oral germ-killer. It was tested as a syphilis treatment in comparison with penicillin and the traditional arsenic compound, salvarsan, shortly after penicillin became commercially available. All three eliminated the syphilis infection, but the drug companies were already set up to produce large amounts of penicillin profitably. Camphoric acid was used to carry bismuth, another heavy metal that was effective against the syphilis organism. (I was interested in using camphoric acid to transport copper, making it able to enter the brain and also causing it to be absorbed via the lymphatic system, by-passing the liver and thus allowing a large dose

to be absorbed without injuring the liver. I swallowed a small amount, and the next morning, noticing that my mouth felt fresh when I woke up, found that my tongue didn't have its customary coating. I have heard that harmless spirochetes tend to grow on the tongue).

Infection with the "trench mouth" organism, *Treponema Vincenti*, was often associated with a deficiency of white blood cells. Another spirochetal disease, Weil's disease, involved fever, headache, vomiting, and intestinal bleeding. Still another type of spirochetal infection was known in Mexico as "pinta," and mainly involved depigmentation of the skin. Early in the century, some of the abnormalities of pigmentation, teeth and hair development, and defects in blood vessels, that had been attributed to syphilis were found to result from a copper deficiency.

For at least 80 years, people have been observing an association between anesthesia and the elimination of viral infections. We have at least three natural anesthetic systems, namely, the GABA system, the endorphins, and the steroids (especially progesterone). These very likely are just three aspects of a single system. Close analogs of the GABA system are already known to have antiviral action.

About 60 years ago, it was commonly believed that women, especially during pregnancy, are resistant to syphilis. Moore[4] states that it is fair to assume that pregnancy is the factor which suppresses the lesions of the disease. This protection may persist over a long period of years and possibly for a lifetime. Spontaneous cure seems in a few instances to have been the ultimate result.

It seems necessary to believe that some substance produced in the course of pregnancy and non-existent in the tissues and body fluids of males and non-pregnant women is antagonistic to the spirochaetae, but whether this is derived from corpus luteum, or other organ of internal secretion, or from the placenta or foetus, is merely a subject for speculation.[5, p. 684†]

Camphor, progesterone, nutritional supplements, and artificial fever have even fewer side-effects than penicillin, and should be tested more widely. The GABA analogs, besides being non-toxic, have the additional advantage of being very cheap. In the pharmaceutical-bureaucratic world, though, this has too often been a fatal defect.

† Serum copper rises sharply during pregnancy, partly as a result of high progesterone levels. Copper provides some protection against iron toxicity.

The close association between immunity and the balance of iron and copper suggests that the iron/copper ratio should be studied in AIDS.[†] The fact that hemoiderosis (a disease of excess iron absorption) occurs mainly in Africans and in transfusion recipients might be expected to relate to the virulence of any infectious disease in those populations. The tumor of Kaposi's sarcoma is often pigmented with hemosiderin. Although the suppressive effect of iron on the immune system is well-known, it is generally ignored, probably because of our society's obsessive belief that "iron is good for you." Iron's effect on the immune system is interestingly examined by June Goodfield in *An Imagined World*.

Since I mentioned the endorphins above in the context of resistance to infections, I should mention that these endogenous peptides are really a family of substances with very different properties; some activate the right side of the brain, others activate the left side.[6] The two sides of the brain have different effects on the immune system.[7] Opiates are powerful suppressors of immunity.[8] I think it is clear that morphine and codeine should never be used when there is an immune deficiency.

[†] Physicians with AIDS or ARC patients are invited to participate in a study of these and other factors. The Health Discernment Laboratory in Santa Barbara, Calif., will do the serum testing. They will do tests on about 12 of each at no charge, but very special handling of the serum is necessary, and instructions are available.

Abnormal Cells in the Uterine Cervix

Townsend Letter for Doctors, January, 1988

THE membranes of the mouth and of the uterine cervix are very similar, and both are susceptible to development of a supposedly precancerous condition, called leukoplakia. Every winter since I moved to Oregon, I developed areas on the inside of my cheeks where they met my teeth, that became spongy and white, and tended to be imprinted with the shape of my teeth, bulging in a way that caused me to bite my cheek frequently. When I learned that vitamin A would control my dandruff and acne, I then noticed that it also normalized my mouth membranes. A dentist noticed my spongy white spots one winter when I hadn't been taking vitamin A, and gravely warned me that it was a precancerous condition, leukoplakia (sometimes called psoriasis buccalis, or dyskeratosis), and that I should have it checked by a doctor frequently. I went home and took vitamin A, and it was gone within a few days. This experience increased my interest in leukoplakia and led me to read more about it. Because of the similarity of cell type in the cervix and in the mouth, I suggested to a friend that she try vitamin A when her doctor told her that she had cervical leukoplakia, and it cleared up right away.

Since the beginning of the century, it has been known that estrogen is carcinogenic, and by the 1940s it was clear that the hormone of the corpus luteum, progesterone, opposes estrogen's effects, and that it consistently prevented estrogen-induced cancers, and sometimes cured them. In the 1950s, it was learned that vitamin A and estrogen have opposite effects, for example, when applied locally to the skin.[1] It was found that, to a very great extent, progesterone could substitute for vitamin A, meaning that a very large fraction of the vitamin A used by the body is used up in making progesterone, from which the other steroid hormones are made.

Considering these facts, it seemed apparent that optimal treatment of leukoplakia would involve a program to lower the chronic background level of estrogen, while promoting progesterone synthesis. It happens that the body spontaneously moves in that direction, if given the right support. With adequate protein (eggs, milk, cheese, shellfish, liver, etc.), the liver removes estrogen from the blood entirely on its first

passage through the liver, in an otherwise healthy organism. In hypothyroidism, the liver metabolism slows, allowing estrogen to accumulate; also, hypothyroidism appears to allow ovarian cysts to develop and to secrete additional estrogen. While the thyroid hormone promotes the elimination of estrogen, it happens to be essential for the production of progesterone. Vitamin A (with cholesterol) is consumed at a high rate by the corpus luteum, when there is adequate thyroid hormone. However, carotene also tends to be accumulated by the corpora lutea, because of its chemical similarity to vitamin A—it is probably a mixture of vitamin A and carotene that gives the corpus luteum its yellow color—but carotene seems to compete with vitamin A for the active synthetic sites, with the result that too much carotene is toxic to the corpus luteum, and is a fairly common cause of failure to have menstrual cycles. Both vitamin A and carotene, like any unsaturated oil, will tend to inhibit the thyroid, so it is important to balance supplements of vitamin A and thyroid; a sluggish thyroid will more easily be suppressed by large doses of vitamin A, but a high level of thyroid activity causes vitamin A to be used more quickly. It is an interesting expression of this biological relationship that one blood protein carries both vitamin A and thyroid hormone.

To back up this basic process of hormone balancing, there are a few things that can be done besides providing animal protein, vitamin A and thyroid. Vitamin E causes vitamin A to be used more efficiently, and besides taking about 100 units orally, a mixture of vitamin E, vitamin A, and progesterone can be applied directly to the cervical membrane. In rapid cell division, and in estrogen excess, folic acid and other B vitamins are used rapidly, so a supplement might be useful. I have usually suggested a dose of one to ten milligrams of folic acid daily for a few weeks, with liver two or three times a week for the other vitamins. Magnesium is not retained well during stress or in hypothyroidism, so a supplement of several hundred milligrams daily is desirable; epsom salts in orange juice is well assimilated and magnesium oxide should not be used because it is not absorbed. Plenty of bright light helps to maintain progesterone synthesis. Vitamin C and zinc are needed, but will probably be provided by the meat, liver, oysters and orange juice which will provide many of the calories; beans, seeds, sprouts, and seed oils, and raw broccoli or cabbage should be avoided, because they can disrupt the hormone balance.

I personally had contact with 35 women who were advised to have a hysterectomy because of abnormal cells found in Pap smears or biopsies, but who wanted to try this approach for a month or two. All of those women had normal tests when they went back to the doctor, usually in two months. Later, I heard that groups had been formed to teach the method, but I haven't heard whether the results continue to be 100%.

Age Pigment

Cause and Effect of Aging and Stress

Healing Village E-Zine, December, 2013

I have written about the many toxic effects of unsaturated oils, estrogen, and excess iron, and how each of these contributes to certain features of aging and age-related degenerative diseases. Now I am going to discuss some of the ways those toxic effects converge, creating a new, "terminal toxin," and how some of the features of aging can result from the presence of this toxin. Rather than using the vague idea of "free radical damage," I think I can show a simple mechanism by which the terminal toxin, lipofuscin, produces the essential features of aging. I suspect that familiarity with this mechanism will be a necessary step in understanding how the high-energy cellular state of youth can be restored.

The word, "lipofuscin," is coming into common usage, so it is worth knowing that its root meaning is "dark fat." The root, fuscus, occurs in the word obfuscate, to obscure. Biologists, who know about the dye called fuchsin, which has nothing to do with lipofuscin, often confuse the words and mispronounce lipofuscin.

In pointing out how oils, estrogens, and iron contribute to aging, I don't mean to distract from their specific toxic effects; rather, those specific effects become more harmful as the organism is weakened by aging.

Lipofuscin, ceroid pigment, age pigment, and liver spots all describe approximately the same thing, though each researcher tends to insist on certain idiosyncratic distinctions, because there is still hardly a "scientific culture" of averaged-out terms and concepts. This is a strange situation, since the substance has been studied occasionally since the first report in 1842, making it scientifically about as old as organic chemistry itself. In 1954, I asked my biology professor (who was in his sixties) what he thought the cause of aging was, and he said some people believed that it was the result of the accumulation in cells of insoluble metabolic by-products, called "metaplasm." His remark was in my mind later when I watched an amoeba dividing under the microscope; it seemed to have become sludgy, viscous, and lethargic, and then as it divided, the new

cells appeared to be moister and more elastic, as if they had diluted some kind of ballast that produced internal friction.

In 1954 there was a report of a girl whose skin turned black from using an ointment containing estrogen. Later, in the 1960s, I noticed that many women using birth control pills developed patchy brown spots on their faces. As I read more about pigmentation, I saw that estrogen, like a variety of irritants, promoted the development of ordinary dark pigment, melanin, in the skin, and that this was different from the liver spots or age pigment that often begin to appear in middle age, and that become so noticeable on the hands, arms, and faces of most old people. As it turns out, both types of pigment are produced by oxidation of smaller molecules which causes them to coalesce into complex masses, but at that point the difference becomes total. Melanin protects against further oxidative injury, but lipofuscin tends to promote further injury. Later, I learned that estrogen was implicated in the production of age pigment, at least in the uterus.[1,2]

Another kind of pigmentation, that is sometimes seen in the skin around the eyes, has been found to contain substances derived from hemoglobin. The heme/porphyrin pigments are interesting in relation to aging, not just because estrogen is known to be involved in the overproduction of the porphyrins, but because lipofuscin has been reported[3,4] to contain the heme group, and because the metabolites of heme (the bile pigments;[5] pyrroles[6]) have been associated with cancer. (As I have mentioned elsewhere, the metabolism of heme produces carbon monoxide, which could produce a self-sustaining respiratory defect.)

That estrogen should have a role in three different types of pigmentation is interesting. What common feature is there in the physiology of these pigments that relates to estrogen?

(Some sources describe a syndrome—Sprinz-Nelson/Dubin-Johnson syndrome, or maverohepatic icterus—that supposedly involves the accumulation of all three pigments—melanin, porphyrin, and lipofuscin—in the liver. The simultaneous formation of different types of pigment might account for some of the disagreements in the study of lipofuscin.)

Melanin is produced in the skin under the influence of ultraviolet light, and in the brain's substantia nigra, it is believed to be produced in relation to a free-radical-generating cycle of dopamine metabolism. Since melanin is an effective antioxidant, it is assumed that its formation represents a defense against free radicals. In the skin, ultraviolet light's

primary "target" appears to be the polyunsaturated fats, in which it produces free radicals. Estrogen—especially when it has been changed into the catecholestrogen form—is known to participate in futile cycles of oxidation-reduction, with the production of free radicals. In 1972, I demonstrated that estrogen powerfully promoted the reduction of the dye, TTC, possibly by such a free-radical mechanism.

Lipofuscin is produced by the over-feeding of unsaturated fats (such as fish oils[7]) and the underfeeding of vitamin E, relative to the amount of unsaturated oils.[8] Ultraviolet light, iron, and aluminum promote its formation, apparently by the production of free radicals. The free radicals generated by estrogen, and by estrogen's promotion of iron absorption, would contribute to the lipid peroxidation. Stress, which is known to intensify free radical production, also accelerates the production of lipofuscin.[9] I have found that estrogen[10] induces cellular conditions that resemble those produced by x-rays and carcinogens,[11] and which probably reflect the production of superoxide or other radicals.

Porphyrins are known to be produced under the influence of estrogen, but anything which interferes with cellular respiration appears to stimulate their production, as part of a mechanism of adaptation to oxygen deficiency that leads to the production of more hemoglobin. Lipofuscin itself contains the heme group, and wastes oxygen in a sort of short-circuit between NADH and oxygen (NADH-oxidase[3,12]). This is also one of estrogen's important effects.

While the formation of melanin seems to be one of the healthy responses to free radicals, and is governed by an enzyme system, lipofuscin seems to be produced nonenzymically, directly by the damaging free radical process itself, and the porphyrins are apparently an adaptive response to oxygen deprivation, rather than to an excess of free radicals.

There would seem to be a sequence of events. If the antioxidant defenses, including melanin formation, are inadequate, then lipofuscin would be formed. If the consumption of oxygen by lipofuscin is sufficient, the heme-synthetic pathway would be activated.

One of the reasons for the lack of interest in lipofuscin has been the doctrine that it is nothing but a little harmless "extra baggage" the cells have to carry, that couldn't account for all of the changes that occur in aging. "Somatic mutations" have been offered as an explanation for the age-related increase of cancer, atherosclerosis, diabetes, arthritis, autoimmunity, and even for the metabolic slowing that is characteristic

of aging. The basic doctrine of aging, held by those in power, has been that, since it involves a generalized slowing of most biological processes and loss of precise regulation, and since the "genes" are held to control all cell processes, the essential changes must happen in the nucleus. Lipofuscin occurs in the cytoplasm, and sometimes is found outside of cells, so its role "must be passive," according to that mainline doctrine.

But exactly the opposite view—that the crucial changes that accompany aging occur in the cytoplasm—fits the evidence more accurately.

For example, there is a steady dehydration of tissues with aging, and a slowing of metabolism. The ability to tolerate stress decreases with age, and chromosomes seem to be easier to damage, and slower to be repaired. According to S. J. Webb, the cell's "bound water" protects against radiation-induced mutations. Since DNA repair is a process that consumes energy, the lower metabolism and low energy production which result from dehydration could lead to an accumulation of mutations. But no one has ever proposed that mutations cause the steady dehydration that occurs with aging. (The dehydration, I think, is most likely a defensive reaction of cells, maybe involving the heat-shock/stress proteins, to preserve the cells' domain of control over their metabolic water, under conditions of limited energy production. I think this resistance against the uptake of water helps to maintain the differentiated state, and to prevent uncontrolled growth.)

If the cell's ability to retain water is partly dependent on ATP, as Gilbert Ling has shown, then interference with energy production could cause the dehydration, in a vicious circle. If lipofuscin interferes with the cell's energy production, or ability to retain water, then it is in a position to create some of the characteristic features of aging. In S. J. Webb's studies of bound water, he found that inositol protected cells by helping them to retain water. His studies are especially interesting, considering Lehninger's observation that "mannitol, or other polyhydroxylic solutes" cause mitochondrial swelling, or inhibit their contraction. (Mannitol is a straight-chain analog of inositol.[13, p. 188–191]) Thyroxin also causes mitochondrial swelling.

In Ling's view, ATP causes cells to retain water in a tightly organized form, and when ATP is seriously depleted, adsorbed potassium is released to become osmotically active, and sodium and chloride enter along with water, which is then in the "loosely held" state of normal bulk water, lacking the special properties of water that had been dominated

by polymer surfaces. This swelling has been called "depolarization swelling," and is partly responsible for the swelling of injured or dying cells. Presumably, less drastic energy changes will cause physiological changes in the amount of organized water, in which water is usefully retained in proportion to the energy level.

While rodents live a year or two—and die in a much more hydrated state than people or animals that live approximately a century—at the end of a rodent's normal life span its cells (e.g., brain and heart) contain as much lipofuscin as the cells of century-old people do. Dogs accumulate lipofuscin about 5.5 times as fast as people do, and people live about 5.5 times as long as dogs. This is just what we might expect if lipofuscin is the "terminal toxin." Loss of cell water would have an influence, but wouldn't be the decisive factor. (The total amount of water in a cell doesn't matter so much, if the energy-producing and functional parts of the cell are deenergized and dehydrated, impairing the cell's responsiveness and adaptability.)

Besides energy production, probably the cell's most basic mechanism of adaptation is the alteration of its structure, which is going on constantly, with the production of new proteins and the destruction of old proteins. This "protein turnover" slows with aging, and the change is mainly on the side of decreased ability to break down old proteins. Lipofuscin directly inhibits the proteolytic enzymes which break down proteins. Unsaturated fats have a similar action, even when they aren't noticeably converted into lipofuscin. They inhibit mitochondrial energy production, which obviously could affect synthetic processes, but it has been known for many years that they also inhibit proteolytic enzymes, although this information tends to be familiar only within certain contexts, such as food chemistry, clot chemistry, immunology, thyroidology, etc.

The mitochondria are continually being repaired and replaced. Inhibition of proteolytic enzymes will cause their repair and replacement to lag, with the result that these crucial energy-producing organelles will "age."

There is evidence indicating that lipofuscin forms in lysosomes and as degenerate mitochondria. With a mitochondrial origin, heme would be present because there are heme-containing enzymes in the mitochondria, but any lipofuscin forming primarily within lysosomes could also absorb heme-like groups from other sources.

It is the heme group which gives the lipofuscin particle the NADH-oxidase function, described by Bjorkerud. Measured in a respirometer, lipofuscin granules respire similarly to mitochondria, except that they do not produce any ATP. As a result, a large amount of lipofuscin will compete with mitochondria for the oxygen which is available to the cell, and will also consume the energy that is available as NADH, and will lower the cell's ability to produce ATP and to function.

When mitochondria are activated, they swell. The swelling-contraction cycle of normal activity is relatively slight. Another kind of swelling, associated with lipid peroxidation, is more extreme, and leads to the destruction of the mitochondria. (Iron, excess unsaturated fats, and many other substances that react with sulfhydryl groups—incuding glutathione—can cause this kind of swelling.) For every molecule of oxygen consumed by cytochrome oxidase, two molecules of water are produced. If lipofuscin is consuming the oxygen, it will produce the water, and the underfunctioning mitochondrion will produce neither ATP nor water, as a consequence of inadequate oxygen. Lipofuscin, therefore, will tend to dehydrate the mitochondria. Anything that inhibits respiration seems to inhibit the physiological swelling. Besides the small contribution of metabolic water, there are probably physical processes associated with respiration that govern mitochondrial water content.

Mitochondrial activation is associated with swelling, and extreme mitochondrial dehydration very likely represents a failure to produce energy effectively, and I suspect tends to cause the destructive collapse of the organelle. But elsewhere in the cell, the vicinity of the lipofuscin will tend to become hydrated, and this wouldn't be subject to the regulating effect of ATP.

Estrogen's early effects include activation of dehydrogenases and peroxidase,[14–16] and it participates in the interaction of NADH and NADPH as well as in the oxidation of NADH.[17–21] The oxidation of NADH is involved in many harmful free radical processes.[22] The most visible early effect of estrogen is to stimulate water-uptake by the cell. How it causes this immediate swelling isn't known, but it probably involves this consumption of oxygen, since simply cutting off the cell's supply of oxygen also causes water-uptake and edema. (Maybe ATP is needed to "extrude" water from the cell generally, as it is in the mitochondria.) The oxidation of NADH tends to raise the pH of the cell, and

by increasing the electrical charge of the proteins this would be likely to cause swelling. I suspect that the normal (respiratory) function of oxygen is to adjust the electrical charge of the cell proteins, in a way that favors ATP synthesis and controls hydration. ATP (which is an acid, and is strongly adsorbed to proteins, influencing their charge) is known to cause swollen mitochondria to extrude water.

Although the exact meaning of the NADH-oxidase NADH-peroxidase activities isn't known, it is interesting that they are so strongly affected both by estrogen and by lipofuscin. Whatever else these enzyme-functions do, they waste oxygen and consume the cell's energy, producing free radicals in the process.

Unsaturated fatty acids have a higher affinity for water than saturated fats do. In the presence of water, they swell. To isolate functional mitochondria, it was discovered that hypertonic sucrose stabilized the mitochondria, apparently by opposing a strong tendency to swell. But when animals are fed a diet rich in unsaturated fats, the mitochondria have a lower swelling tendency than do those of animals that are "deficient" in polyunsaturated fats. This is the opposite of what might be expected from the physical behavior of the unsaturated fats, so the difference probably involves the metabolic activity of the mitochondria, rather than their physical chemistry. ("…the active swelling stimulated by respiration has a high temperature coefficient, which is consistent with a chemical or enzymatic process…"[13, p. 184–185]) For one thing, the unsaturated fats simply block respiration by blocking the electron transport chain, and by inhibiting cytochrome oxidase. In fetuses and young animals up to the time of weaning, one site of the cardiolipin molecule, which is essential for cytochrome oxidase function, contains the saturated fat, palmitic acid. After that, as the animal's respiratory activity declines, the palmitic acid is replaced by linoleic acid. At the same time that respiration is being inhibited by the unsaturated fats, lipofuscin begins to accumulate, further interfering with respiration, by consuming oxygen outside the mitochondria.

When fed a diet high in unsaturated fat and low in vitamin E, lipofuscin forms rapidly, and the incidence of cancer and other diseases of aging—including diabetes—increases greatly. (Regarding glucose metabolism, Barnard, et al.[23]; many more references are given in my article on diabetes, scleroderma, and oils.)

It is interesting that the first publication identifying dietary fat as an essential cause of cancer (1927) appeared almost at the same time as the demonstration[24] that a substance resembling lipofuscin could be produced by bubbling oxygen through unsaturated fat (fish oil). Various types of unsaturated fish or seed oils have since then been used to produce lipofuscin *in vivo* and *in vitro*.

Hartroft and Porta[8] demonstrated that the pro-oxidant metals, especially iron, accelerate the formation of age pigment, and recent experiments confirm those observations.[25] Aluminum and silicon, which have a role in brain and blood vessel aging, also have a role in the formation of age pigment.[26]

My observations of extracts of aged tissue, soaked in ether or pyridine, showed an absorption spectrum in the ultraviolet frequencies that indicated the pigment was a complex mixture with unsaturated fats, but with the specific absorption indicating the presence of heme or related material.

When artificial lipofuscin, made by ultraviolet irradiation of mitochondrial preparations, is added to cell cultures, the cells act as if they had aged suddenly, and then die.[27]

Similarly, when mitochondria are extracted from old cells, and injected into young cells, the young cells behave as if they had aged.

One of the remarkable things about the NADH-oxidase described by Bjorkerud is that it is cold-inactivated. I have argued[10,28] that estrogen activates enzymes of this type, but a mere excess of water could have a similar function, and if these granules produce their own water, they will tend to support the condition which activates themselves, while also tending to decrease the metabolic activity of mitochondria. Where the water is being produced, there is a lack of ATP, and where the ATP is being produced, there is a limiting lack of oxygen. While estrogen causes cells to take up water immediately, before any other cellular change is seen, my argument has been that it makes the cellular water more "bulk-phase" like, with less of the structure (vicinal water) evident in water near surfaces; this argument is based on NMR studies of water in tissue treated with estrogen.[10] The damaging effects of estrogen on mitochondria,[29] in this view, might be the result of changing enzyme activities by affecting water structure, as well as of causing a redistribution of water between cellular organelles.

Estrogen causes changes in collagen synthesis that resemble changes occurring in aging[30,31] and in oxygen deprivation.[32] The theory that cross-linking (hardening) of collagen causes aging is popular,[33] but it seems odd that the idea of interactive factors in hypoxia—estrogen, collagen, and lipofuscin—hasn't been of greater interest. Hypoxia,[34] radiation, and stress (lipofuscin accumulation with restraint stress[35]) like estrogen, cause accumulation of collagen and lipofuscin, and lipofuscin contributes to hypoxia and stress. The fact that puberty in girls is accelerated by unsaturated fats, and delayed by their deficiency, is just one of the many indications of the close connection between estrogen and the unsaturated fatty acids.

The doctrine that radiation causes cancer simply by causing mutations has grown up in the scientific culture that has paid essentially no attention to lipofuscin. All sorts of ionizing radiation produce free radicals in unsaturated oils, and so naturally radiation will contribute to the formation of the age pigment. In the depleted, low energy state that develops when a large amount of lipofuscin has accumulated, chromosome damage will occur, and will not be repaired as it is in the youthful high energy state. Mutations in themselves don't cause aging,[33,36†] but aging creates a disposition for mutations to accumulate. (It was found that men who exercised before breakfast produced large numbers of chromosome breaks. The energy provided by breakfast made a visible difference in the amount of chromosome damage produced by exercise. The chronic low energy state that results from being full of rancid fat must amplify the damage done by ordinary stress.)

Minimizing radiation, of course, is important, and if we aren't primarily worried about radiation as a direct mutagen, the comforting thought of a "threshold of safety" disappears. The same principle applies to the avoidance of environmental toxins (so many of which are estrogenic), since the factors that promote age pigment all seem to be additive. The age pigment is a final common pathway in which many types of damage converge, in the way many different factors converge in the drying of paint. By depleting the cell's energy, lipofuscin accumulation causes trivial challenges to become increasingly harmful, in a vicious circle that tends to accelerate the production of lipofuscin.

† See quotation at the end.

Some of the factors that significantly accelerate the formation of lipofuscin—dietary polyunsaturated fats, deficiency of vitamin E and selenium, and excess iron—are things that can be manipulated without great effort. Some of the proven factors that retard its formation, such as a low calorie diet, are not so easy to sustain, and require some study.

If a "program in the genes" controlled the rate of aging, dietary modification should make no difference at all, but calorie restriction slows the rate of aging, as it slows the rate of lipofuscin formation.[37,38]

The doctrine of "programmed aging," and the Hayflick doctrine, maintain that cells have an innate capacity to undergo about 50 divisions, and that "aging" consists of having used up their limited capacity for division. It is clear that the medium in which the cells are cultured affects their ability to multiply, and that serum from old animals slows their growth. The experimental data from human cells cited by Hayflick oddly fail to support his theory. For example, cells from a sick 87-year-old person underwent 29 divisions in culture, and those from a 26-year-old person killed in a car accident were able to divide only 20 times in culture. Cells from a single individual, in different (repeated) cultures show very different "limits."[39] The appropriateness of the culture medium for the particular needs of the cells seems to be the issue, and all cells do have a "memory" or "program," reflecting their developmental state and function. Because of this cellular memory or inertia, a damaged condition might be passed on to daughter cells, and even to a subsequent generation or two, before full vigor can be restored. Historically, these "lingering effects" of the environment have been called "dauer-modifikationen." I believe our present level of pollution, by this sort of lingering effect on development, is going to produce an increasing incidence of birth defects, immunodeficiency, accelerated aging, and cancer, if biological remedies aren't found to neutralize its effects. The harmful effects of estrogen—DES, for example—persist for generations. Besides the hundreds of estrogenic chemicals accumulating in the environment, medical estrogen has been prescribed for approximately 200 stupid purposes. Harvard Medical School lent its prestige to the deadliest and most anti-scientific of these promotions, and government agencies have endorsed the fools and colluded with the criminals. Similar medical/industrial/governmental conspiracies have operated in many other areas, notably in the use of iron and seed oils.

The Possibility of Remedies

There is evidence that cells can clear themselves of lipofuscin, but the mechanism isn't understood. As a result of low oxygen tension in the fetus, lipofuscin appears, but then disappears after birth. The composition of this material could be different from the material that develops later, but the greater metabolic activity of the newborn is probably related to the ability of cells to destroy it or to excrete it. Recently, it has been proposed that a variety of psychotropic drugs promote its excretion,[40] but most of those drugs have serious side effects. In cultured brain cells, it was found that vitamin E and ethyl alcohol promote its disappearance. Since alcohol's toxic effects largely derive from its interactions with unsaturated oils and iron, a small amound of alcohol might be useful in clearing lipofuscin. I have often seen topically applied vitamin E with progesterone remove age spots from the skin. In younger (age 45 to 55) women who have developed the spots while using estrogen, the spots sometimes disappear when they stop using estrogen. In much older people, the use of vitamin E and progesterone has sometimes only caused the spots to slowly become lighter, during several months.

Since lipofuscin contains proteins and metals as well as fats, it has been suggested that activation of proteolytic enzymes would facilitate its removal, but it is partly the inhibition of proteolytic enzymes by lipofuscin that makes it a difficult problem. The low calorie diet which delays the formation of lipofuscin is known to increase the activity of proteolytic enzymes, and I think this is largely the result of reduced exposure to unsaturated fats. According to the Shutes' research, vitamin E facilitates the clearing of blood clots by activating proteolytic enzymes. At the time they were doing their research, it was recognized that estrogen and unsaturated fats inhibit proteolytic enzymes. While the heart-disease industry has done a lot of pharmaceutical research on the regulation of the clotting process, there is much less research on the proteolytic enzymes which remove clots. The Shutes introduced the issue more than 50 years ago, and I suspect that their observations showing that vitamin E, thyroid, and progesterone protect against heart disease by opposing the clotting effects of estrogen (and unsaturated fats) came too close to saying that the problem can be solved without the help of the great drug industry. A solution for degenerative diseases which shows

estrogen and polyunsaturated oils to be essential parts of the problem is not one that will find many research grants.

To me, the chemistry of lipofuscin indicates that we should minimize our exposure to unsaturated fats, iron and other metals, and estrogen, while cautiously exploring the ways to prevent their cumulative damage. Since many things promote oxidation in one context and inhibit it in another, caution is important in exploratory research. Copper, for example, can cause harmful oxidation, but it is required for melanin synthesis, superoxide dismutase, cytochrome oxidase, and other enzymes, and its deficiency leads to intense oxidative damage from iron. When there is clear evidence that a particular form of copper is safely assimilated, it might be a desirable food supplement. At present, I think mollusks and crustaceans are the safest sources of copper.

Many "antioxidants" that are being promoted for medical/nutritional use are seriously toxic, even mutagenic or carcinogenic. The "adaptogen," mildronate, protects mitochondrial ATP production by restricting the oxidation of long-chain fatty acids. This type of antioxidant seems to reinforce natural protective processes,[41] and is not likely to have the toxicity of the phenolic, or polyphenolic, antioxidants. Other particular therapies for aging might include direct restoration of ATP and hypoxic (high altitude) adaptation to stimulate the regeneration of mitochondria.

Currently, I think the most important issue is to find foods that are practically free of the polyunsaturated fats. Low fat milk and cheese are suitable, and are desirable because of their low iron content, but are not ideal for an exclusive diet. A supplement of vitamin E and coconut oil should have a significant effect on the rate of aging : the effect of coconut oil is to reduce the need for vitamin E, to act as a dilutional chain-breaker in free radical propagatioin, and to provide energy at a high level to repair cell damage. While unsaturated oils contribute to the inlammatory process (and there is serious question as to why evolution would produce the mechanism of inflammation, since its effects on balance seem harmful), coconut oil doesn't, and the inflammatory "eicosanoids" made from the "essential" fatty acids probably contribute to the formation of age pigment in certain situations, such as in atherosclerosis. Since free radicals are produced in the formation of prostaglandins, aspirin and other antiinflammatory drugs have a sort of antioxidant effect, which might explain their apparent role in the prevention of Alzheimer's disease.

The thyroid hormone itself has been found to be protective against lipid peroxidation, and even against radiation damage, and thyroid function is promoted by coconut oil. Proper thyroid function minimizes the production of adrenaline, and adrenaline—like estrogen—increases our exposure to fatty acids. Potatoes and many fruits are fairly low in the unsaturated fats and iron. The ketoacid equivalents of the essential amino acids are found in some plant materials that are very low in unsaturated fats and iron. When the right combination can be found, it would be possible to have varied foods that provided calories, minerals and vitamins, with either protein or a protein equivalent, which wouldn't lead to the accumulation of unmetabolizable fats and metals.

An important, but neglected, aspect of respiration, resulting from proper thyroid function, is the production of carbon dioxide. Carbon dioxide has some remarkable properties, including the regulation of circulation and mineral balance. I believe it probably has a direct role in the production of ATP, and by its physical-chemical effects, it might be an essential factor for activating the enzymes of the lysosomes, which have the capacity to clear age pigment from cells. The effects of diet, hormones, and oxygen deprivation on aging and lipofuscin could be mediated importantly by their effects on the production of carbon dioxide.

An outstanding feature of the "false respiration" of lipofuscin is that it produces no carbon dioxide.

Aging Ovaries: Not the Eggs

Townsend Letter for Doctors, August/September, 1995

A few months ago public television ran a long program on the menopause, in which a rather glamorous woman physician said some shockingly ignorant things about the ovaries and menopause. I went to some book shops, to see what she might have been reading, or hearing in conversation.

One writer thought it would be nice to change the name of the menopause to "the pause." Another said it is too judgmental to say that the ovaries "fail" at menopause, and that they are really just maturing. Those concerns with terminological politeness remind me of Woody Allen's remark about death—that it is nature's way of telling us to slow down.

All of these current paperback books about menopause subscribe to the same doctrine about reproductive aging. Uniformity of opinion creates an environment in which publishers who want to sell a lot of books feel that they have to publish things that don't disturb the reading public. Books about menopause become books about an attitude toward menopause.

Even people who like to say that ovaries "don't fail" at menopause describe a theory in which menopause and its consequences are the result of the disappearance of eggs from the ovary. That theory is so simple it can be described in three short sentences, none of which is true: (1) ovary runs out of eggs; (2) ovulation produces hormones, so you can tell when ovulation stops because the ovaries stop producing hormones; (3) menstruation stops because ovulation has stopped. Those principles are surrounded by various corollaries. "Estrogen is the female hormone." "Estrogen deficiency accelerates aging." "Treatment with estrogen makes you more feminine." "Progesterone deficiency is the result of anovulatory cycles."

Many experimenters have demonstrated that old animals that have become infertile keep producing eggs. Several experimenters[1] have removed eggs from the ovaries of old animals, and transplanted the fertilized eggs into young animals, where the embryos were able to implant and develop normally.

I found that old animals had too little oxygen in their uterus to keep the embryo alive at the time it would normally be ready to implant itself in the uterus. Giving estrogen to a young animal causes a similar lack of oxygen in the uterus, and prevents implantation of the embryo.

At the time old animals would normally have become infertile, they remain fertile if they are given a supplement of vitamin E and progesterone.

It is now established that aging animals, at the time they become infertile, are deficient in progesterone, but still produce estrogen. Even in young individuals, when stress occurs around the time of ovulation, interference with progesterone production will prevent implantation. If progesterone becomes deficient after the embryo has become implanted, miscarriage occurs.

Estrogen, acting alone or with insufficient progesterone, causes spasms in the spiral arteries that provide oxygen and nutrients to the endometrium. This seems to be the basis for menstruation, and is also believed to be a factor in miscarriage.

About 30 years ago, researchers began to understand that reproductive aging was not caused by the lack of eggs, and the aged uterus was able to support pregnancy if it had the right hormonal support. Interest turned to the brain cells in the hypothalamus which regulate the pituitary. G. H. Zeilmaker[2] was one of the first to suggest that ovarian hormones caused the brain to age. More recently, P. M. Wise[3,4] has clearly demonstrated that estrogen exhausts the cells which inhibit the pituitary gonadotropins, with the result that even abnormally high levels of estrogen are unable to turn off the pituitary secretion of the hormones that drive the ovary. Estrogen itself can impair the ovary's ability to produce progesterone, but the continuously high secretion of gonadotropins disturbs the ovary, the adrenals, and (according to recent observations) even the uterus.

Stress, especially when augmented by estrogen, leads to injury, exhaustion, and aging. The uterus and ovaries participate in the response to stress, but (as Zeilmaker and Wise have shown) the brain proves to be more directly involved in menopause than the ovaries or uterus. Coordination turns out to be crucial for complex processes such as ovulation, fertilization, and implantation. The destruction of the nerve cells that regulate the pituitary makes coordination impossible.

The issue of "running out of eggs" can be settled simply by demonstrating the presence of viable eggs at the time reproductive ability has ended. In the 1940s, menopause was "explained" in terms of an estrogen deficiency, without a basis in fact, and now an "egg deficiency" is combined with the "estrogen deficiency," compounding the confusion. Facts aren't everything in science;[†] it is necessary to look at the context from which these ideas develop.

Two of America's most productive researchers in reproductive physiology, Edgar Allen and Herbert M. Evans, made observations that they believed showed that the germinal epithelium of the ovary goes through a cycle of cell proliferation that produces a new generation of oocytes during each menstrual cycle. It is recognized that new egg cells appear in the ovaries of adult prosimian primates, and at puberty in cats and pigs. Observations of newly developed egg cells have been reported in some other species. But the dominant view prefers to see the number of egg cells declining from birth, or earlier, with absolutely no new egg cells being formed later.

During gestation and infancy, the gonadotropins are very high. These hormones decline during childhood, during the time that the number of egg cells is so visibly declining. The high level of the gonadotropins during infancy hasn't been explained, but it is reasonable to suppose that it has something to do with the development of the ovaries, since a "developmental" function can be demonstrated for the gonadotropins in the ovaries and testes of older animals.

The number of brain cells peaks a few months before birth, just as the number of egg cells does. Many people have argued that this somehow means that brain cells are incapable of dividing after infancy, though there is no factual basis for making that argument, and in fact

[†] Since the 1930s, estrogen's toxic potential has become very clear. However, the estrogen industry doesn't want people to understand that estrogen is a shock hormone with pro-aging effects. Histamine mimics estrogen's effects on the uterus, and antihistamines block estrogen's effects.[5,6] Estrogen mimics the shock reaction. Stress, exercise, and toxins cause a rapid increase in estrogen. Males often have as much estrogen as females, especially when they are tired or sick. Estrogen increases the brain's susceptibility to epileptic seizures, and recent research shows that it (and cortisol) promote the effects of the "excitotoxins," which are increasingly implicated in degenerative brain diseases.

adult brain cells are now known to be able to divide. (That is true of heart cells, too.)

In a variety of tissues, it can be shown that the presence of mature cells inhibits the division of other cells. If part of the liver is removed, the remaining cells divide to replace the lost tissue. If the skin is cut, cells divide to help fill in the defect. If there is an adequate number of egg cells, this principle suggests that there is no need to produce more. There is a treatment for polycystic ovaries called "wedge resection." This can reduce the production of masculinizing hormones. By analogy with other tissues, it seems likely that the removal of a mass of malfunctioning tissue leads to the growth and development of new cells which function the way a new ovary would. Regeneration seems to be a capacity of every tissue, given the right environment. If the ovary were studied after such treatment, I suspect that "new eggs" would be found. (But even in the seemingly simple process of healing a wound in the skin, there is still disagreement as to the relative contribution made by local cell division, and the invasion of the region by structural cells from elsewhere in the body. The appearance of a cell can be misleading; histology is often a matter of making educated guesses. For example, white blood cells can look like epithelial cells.)

Although the question of whether all the woman's eggs are in existence at or before birth doesn't logically have anything to do with the other question, whether there are still eggs in the ovary at menopause, there is a reason that people connect them. This has to do with the idea of a "germ line" as distinct from the "somatic cells." The eggs are "from the germ line," all the rest of the body (and much of the ovary) is a different sort of stuff. The "germ line" has the special property of immortality and it is "isolated" and independent.

The body is susceptible to being modified by the environment, and is mortal. These are the traditional formulations of the idea, and the people who learn their orientation from textbooks are not necessarily conscious of how the ideas fit together. For biologists of my professors' generation, these ideas seemed to be a sacred core of biology, but with their death, maybe biology can be liberated.

August Weismann, working at the end of the last century and the beginning of the 20th century, created the basic ideology of genetics, to combat the idea of the inheritance of acquired characteristics, which had been supported by Darwin and others. He argued that the hereditary

substance, or germ plasm, was derived only from preexisting germ plasm, and couldn't be formed anew, or modified by the environment. It created every part of the perishable body, by a process in which traits were segregated, so that the germ plasm contained the full complement of hereditary material, and each part of the body contained only the limited fraction needed for its characteristics. Thus, the body was inferior created material, while the germ line was the immortal creative stuff. Since the body adapts in response to the environment, it had seemed that these changes would be passed on to descendants, until Weismann's argument showed that it was only the perishable, dead-end body lacking the hereditary principle which was adapting. The germ line was somehow isolated from the body and from the environment.

Weismann's theoretical germ line became identified with the chromosomes and the genes. His theory was shown to be simply wrong, in that each type of cell in the body contains a full complement of chromosomes and genetic information. Although his facts were wrong, his ideology became deeply embedded in the culture of genetics. To keep the idea that the "germ line" is somehow something distinct from the body required a special effort, once the chromosomes were seen to be identical in every part of the body. Weismann's whole point in his "germ line" idea was to show an absolute distinction between the body and the hereditary substance. If his ideology that had been built to deny the inheritance of acquired characteristics were to be saved, the isolated germ line would have to be found elsewhere than in the chromosomes.

The idea of "germ line (or *Keimbahn*) determinants" now took over, and was believed to be something in a certain spot in the egg. As the egg divided, into cells that look very much like each other, the cells which came from that part of the egg represented the germ line. As the embryo developed, the region that seemed to be traceable back to that part of the egg, represented the germ line. As the gonad began to grow, cells from the region representing the germ line were thought to travel over and invade the gonad, where they multiplied into vast numbers, but always remained the same isolated strain of germ cells with their "separate" history that could be traced back to the determinants in the special place in the egg. During the early days of embryonic development, these immigrant cells looked exactly like their neighbors which were somatic cell sprouts from the embryonic kidney region.

If it weren't for the ideology of absolute isolation of the hereditary substance, an embryologist might have suggested that cells or material of one part of the embryo induced a specialized, differentiated state in some cells that happened to be suitably located. If the cells derived from that certain part of the egg didn't carry unique genetic material—and they didn't—then what they carried with them was an incipient state of differentiation. Why the big deal about that particular history of differentiation? It was because the ideology that motivated Weismann was still active, and its purpose was to argue that only the "gene" was the creative productive source, and that the body—the "somatic cells"—was the passive product, whose adaptations meant nothing in the long run. This has been called the "central dogma" of genetics, that information flows only from the gene to the cell, and not back from the cell to the gene. That ideology forced geneticists to deny the existence of RNA viruses (including retroviruses such as the HIV-"AIDS" virus), and is still active in blocking research on the prion or scrapie virus, which is a protein. To say it bluntly, many highly respected biologists acted stupidly because they blindly believed in a false ideology.

Incidentally, this ideology was always impossible for horticulturists to accept, since they were in the habit of grafting (cloning) vegetative (somatic) parts of plants, which would then produce flowers and fruits. For them, the "germ" was often a product of the "body." Luther Burbank's work was consistently ridiculed by the academic biologists, who believed his achievements were impossible, that is, fraudulent. Many of Burbank's perceptions have been supported by recent evidence, but they couldn't be accepted by people whose ideology of the germ line/somatic distinction seemed to be contradicted by his work.

Another problem with the doctrine of the germ line was revealed when embryologists separated the embryo at a very early stage into two groups of cells, and found that each was able to grow into a complete animal. The idea of the germ line predicts that one member of the pair of twins could get the ability to reproduce while the other would be sterile. Some important ideas can survive their disproof.

It is exactly the same academic ideology of the priority of the germ line which blames the whole complex process of reproductive aging on the mechanical process of an "ovary running out of eggs." The ovary doesn't run out of eggs, and running out of eggs would have no great consequences if it did happen, because the main events in ovulation are

produced by cells other than the eggs. But the ideology says that the "germ line" controls everything, and the eggs are the germ line. In other words, genes control the organism, and eggs control the woman.

I think it will be instructive to consider the three steroid secreting glands—ovaries, testes, and adrenals—together, to see what they might have in common. In the testes, it is generally believed that pituitary gonadotropins regulate steroid synthesis and gametogenesis. In the ovaries, the gonadotropins also regulate the production of steroids, and—to some extent—the production of eggs, if not the whole gametogenic process. In the adrenal, ACTH governs the production of cortisol and sex steroids, and the transformation of the glomerulosa cell type into the other types, which secrete those hormones.

The outer layer of cells in the adrenals can form the other two cell types, and since stress ACTH converts them to the other types, new ones must be formed. If the inner layers are removed, the whole adrenal cortex can regenerate from the outer layer. Obviously, if stress causes cells to multiply and differentiate, cells are disappearing from the inner layers.

When I was in graduate school, immunologists were aware that new cells were continually appearing in the thymus gland, but the gland didn't get bigger, and there was no visible trace of dying cells. At that time, it was considered a major puzzle, but gradually it came to be understood that a special kind of cell dissolution (called apoptosis) was occurring that accounted for the missing cells.

In the testes, apoptosis or cell dissolution is always occurring, even though sperm cells are being produced and leaving the organ.

In the ovary, "waves" of egg cell degeneration are constantly taking place in young women. Radioactive labelling that has been used to argue that egg cells aren't being replaced seems to show that there is continual cell division in all the other ovarian cells. Interestingly, those researchers didn't seem to be interested in this apparent regeneration of the other parts of the ovary.

Apoptosis always seems to be part of a shaping process of the organ in which it occurs. Regeneration provides new cells, apoptosis recycles the substance of a certain fraction of the tissue's cells. We are just starting to notice that various hormones inhibit or promote apoptosis, and so participate in the "shaping" of the organism. In many systems, it seems

that the need for a cell type or function calls it into existence, while idleness makes a cell susceptible to dissolution.

I have been referring to the "pituitary gonadotropins," and deliberately avoided referring to them as LH—luteinizing hormone—and FSH—follicle stimulating hormone—because their names reflect a theory of what they do. In some textbook descriptions of testicular function, for example, it has been said that LH produces testosterone, and that negative feedback from testosterone suppresses LH, while FSH governs the formation of sperms. That description is completely worthless, and probably was largely built up by analogy with their supposedly neatly divided functions in the ovary, reflected in their names.

These gonadotropins participate in the development, maintenance, and functioning of the ovaries, and their effects depend on their timing, their balance with each other and with the steroids produced by the ovaries in response to their stimulation, and their actions are modified by many other factors, ovarian, nervous, pituitary, uterine, and immunological. During youth, the system functions in a coordinated way, with ovulation as a consequence. During aging, the crucial changes appear to be a decreased ability of the ovary and the brain to produce progesterone. Thyroid hormone, cholesterol, vitamin A and efficient cellular respiration are essential factors for synthesizing progesterone. Accumulated iron, unopposed estrogen, and impaired use of cholesterol and oxygen are factors known to contribute to the widespread and variable damage to the system of coordination.

Two things can cause the pituitary to secrete excessive amounts of the gonadotropins: A deficiency of the steroids, and damage to the steroid sensing nerves that regulate the pituitary. When an ovary is moved (transplanted into the spleen) so that its hormones are destroyed before getting to the brain, there is hypersecretion of gonadotropic hormone,[7–9] and tumors develop in the ovary. The interpretation, that hypersecretion causes the tumors, is supported by other observations, e.g., that removal of one ovary increases the chance of developing a cancer in the other ovary and that prolonged use of estrogen (known to create the conditions for later hypersecretion of gonadotropin)[3,4] increases the risk of ovarian cancer after menopause.[10]

Psychologists have noticed that naming an object according to a certain function often limits the way people will be able to use it. This happens in science. If we know one function of a substance, and name

it for that function, we will find it harder to think of its other possible roles. Hans Selye argued that steroids, for example, should be named according to their place of origin, rather than by a single aspect of their function. I think this applies even to the phrases "male hormone" and "female hormone": it's better to think of them in terms of their origin, and not to count on them to promote femininity or masculinity.

A note about "the female hormone." In the absence of the testicular or "male" hormones, animals differentiate as females.

Progesterone is an anti-androgen, and blocks testosterone's effects. When testosterone is given to newborn or very young rats, it sets up a male pattern of hormone development, but if progesterone is given at the same time, that doesn't happen. Progesterone prevents the differentiation away from the basic female path into the male specialization. Later in life, a deficiency of progesterone in a woman can again lead to masculinization of some features, such as musculature and facial or body hair. When progesterone is given to men in large doses, it blocks various typically male processes, such as growth of whiskers. In the brain, it has a protective function in both sexes.

Estrogen promotes cell division, and is involved in essentially every tissue, in both males and females. If it is to be called a "female hormone," maybe it also has to be called "a male hormone." It does have to be present for breast development, though it is just one of many factors. In this instance, it is contributing to feminization. In other instances, it seems to contribute to virilization.

At menopause, estrogen excess can promote the production of androgens, in the absence of progesterone, which tends to defeminize the woman. This is often a result of stress, and sometimes is a consequence of hypothyroidism. In situations of this sort, estrogen is seen not to be a feminizing hormone; it is unable to neutralize the male hormones the body produces in response to the estrogen excess.

Currently, estrogen marketing emphasizes appearance and the danger of osteoporosis. Evidence occasionally turns up implicating estrogen in thinning of the skin and bones.[11]

Aspects of Wholeness

Townsend Letter for Doctors, October, 1990

> "That a meeting-point between Biology and Physical Science may at some time be found, there is no reason for doubting. But we may confidently predict that if that meeting-point is found, and one of the two sciences is swallowed up, that one will not be Biology."
>
> — J. B. S. Haldane

HOLISM is the observation that, although natural objects can be resolved into their parts, the parts are to some extent shaped by their participation in the whole object. For example, in organic chemistry it is recognized that the reactivity of an atom or radical is modified by adjoining parts of the molecule, by the solvent, etc. Holism would never have been named, except that it is so common in our scientific tradition for someone to say "We know all there is to know about the parts (atoms, surfaces, fields, genes, etc.), so we can foresee the result of their combination." Good engineering involves knowing the properties of the materials so thoroughly that accurate predictions can be made about their behavior in new structures, but good science requires a willingness to accept the unpredicted when it occurs.

Holism, or a non-dogmatic attitude toward the world, recognizes individual uniqueness, rather than averages, and is likely to look for complex causes (especially environmental influences), rather than too easily ascribing traits "to the genes."

Historically, a reluctance to distinguish our present knowledge from possible knowledge, and to distinguish our definition of something from its real existence and fullest potential, has characterized most of the people who oppose holism, and call themselves reductionists. Consciousness, perception, sensation, pleasure, and intention have often been omitted from the world described by reductionists. If we are going to understand life and its possibilities, then it seems that we should begin with an appreciation of its "liveliest" aspects, as an essential dimension

of our thinking, even if we are going to work with some of its relatively inert aspects, such as viral genetics.

The relation of energy to structure is, I think, the central question of biology. (The importance of the same question for the physical sciences might indicate in a rough way how Haldane's predicted "swallowing up" might occur.) The ideas of resonance and hysteresis, which are only vaguely defined in physics, have to do with the interaction of energy and structure on various levels of complexity and organization, and are examples of physical concepts that can gain meaning and clarity from biology. When energy flows through matter, order accumulates (as a result of resonance and hysteresis, for example), but we hear so much about "entropy," "randomness," and "symmetry" that we forget most of the formative processes in the material world.

Human (and ecological) health obviously should have the benefits of holistic science, but the actual situation is that biology and medicine have become very product-oriented, and holistic considerations are increasingly left to a variety of "fringe" occupations. Many of these alternative approaches are concerned with the idea of "energy" as the key to health, but in general they lack simple and effective methods for optimizing biological energy, and often use counter-productive methods. In the following pages I will show how some of the most important achievements of ordinary science can be retrieved from the distortions of the medical promoters, and made available for holistic use, that is, for appropriate use.

Non-Genetic Biology

The word, "gene," itself contains an ideology, since it implies origin, or genesis, though its main meaning is something like "a unit of continuity." Building on the word's connotation, dogmatic geneticists explicitly stated their "central dogma": that information flows only from DNA to RNA, and only from RNA to protein. When Temin and Baltimore described the "reverse transcription" of DNA from RNA, all of the professional biologists I talked to said flatly that they didn't believe it was possible. Even when no one was threatening the addition of "information" to the chromosomes, the dominant belief among biologists was that development was closely controlled "by the genes," because the body owes its genesis to the genes. Intelligence, body proportions, and senescence

were said to be "specified" or "governed" or "programmed" by the genes. The "congenital" condition was often taken as the "genetic" condition. Textbooks said that the maternal influence was only "genetic," because the fetus was "insulated" from events in the mother's body (just as the "germ line" was isolated from events in the rest of the body). Although many kinds of experiments showed both prenatal and transgenerational influences of the environment on intelligence, body proportions, and rate of aging, the genetics-reductionist school ignored them, and defined themselves as the only scientific school of biology.

Mechanisms of Aging

Professor Soderwall and his students at the University of Oregon had shown that the corpora lutea (areas in the ovary which mainly produce progesterone) appeared to fail in aging hamsters, and that vitamin E supplements could extend fertility by a significant amount. His group showed that "aged ova" were not responsible for infertility, but rather that the uterine environment was not suitable for implantation. Soderwall had also demonstrated that excess estrogen could cause failure of the pregnancy at any point, from failure of the embryo to implant, to resorption of the fetus at a late stage of pregnancy.

Although I had investigated the association of estrogen with cancer, and knew from my own experience with migraines that stress, diet and hormones interacted in powerful ways, when I began to investigate the oxidative metabolism of the uterus I didn't realize that it would involve a convergence of several of my main interests. I was familiar with Otto Warburg's famous idea that cancer is caused by a "respiratory defect," and I knew that aged tissue had a diminished respiratory capacity. The textbooks indicated that estrogen deficiency and "aged ova" were responsible for senescent infertility. I found that the uterine endometrium of old animals often consumed oxygen at a high rate, and showed other signs of being under the influence of excessive estrogen. As I tried to understand this, I saw that several things could contribute to a high rate of oxygen consumption. Either too much estrogen, or too little progesterone could have the same effect, since it is the ratio between these hormones which controls their effects. A vitamin E deficiency increases oxygen consumption, and too much unsaturated fat has the same effect. In a vitamin E deficiency, unsaturated oils are oxidized in a way that

produces "age pigment," also called ceroid pigment or lipofuscin. This pigment consumes both oxygen and fuel, but produces no usable energy. Estrogen excess synergizes with a deficiency of vitamin E to intensify the formation of this pigment. Partly, this might be because estrogen is a powerful stimulant of iron absorption, and iron is involved in the peroxidation that produces the pigment. But low oxygen concentration is what causes the iron to become active in peroxidation, and estrogen acts in several ways to decrease the availability of oxygen.

The way in which estrogen prevents or terminates pregnancy seems to be by causing the uterus to consume oxygen at such a high rate that there is no oxygen available for the embryo, which has a high requirement for oxygen beginning on the day that it normally implants. The chronic or cumulative effects of estrogen, leading to formation of lipofuscin, happen to act in the same direction as estrogen itself, causing oxygen to be reduced, especially in the uterus, but in all other tissues, too. Estrogen excess can also destroy the corpora lutea, interfering with the production of progesterone. Progesterone's effect in pregnancy is to assure the availability of oxygen and nutrients for the embryo, but it also has the general effect of inhibiting the formation of lipofuscin, and of other aging signs, by improving metabolic efficiency. (Progesterone is unusual among the anti-stress steroids in having no harmful side-effects.)

Although my work confirmed the other research that had been done in Soderwall's lab in the preceding 25 years, the idea that estrogen's influence appears to increase with aging, and even to contribute to the process of aging, was contrary to the doctrine that has been promoted by the pharmaceutical industry. Nevertheless, as I read more, I saw that there was really no evidence contrary to what I had seen in my own work. What existed was a web of interpretation which existed to sell estrogen treatments. Even the fact that estrogen causes abortion was "ignored," very consciously, until the industry had fabricated a more acceptable rationale with which to sell its "contraceptive" pills.

The idea of many factors acting in the same direction, and tending to have a cumulative effect, seemed to me to have a general biological significance. It seemed to be part of the answer to the question of what it is which is lost, or accumulated, during aging, which accounts for the decreased ability to adapt to the changing environment. It seemed to say something about the nature of Warburg's "respiratory defect" in cancer.

The thyroid hormone, which governs respiration, is suppressed by estrogen, and by unsaturated fats. The wasteful metabolism of estrogen dominance tends to use up glucose, and is likely to activate the stress hormones, including cortisol.

The main features of aging can be produced directly by administering excessive amounts of cortisol. These features include atrophy of skin, arteries, muscle, bone, immune system, and parts of the brain, loss of pigment (melanin), deposition of fat in certain areas, and slowed conduction velocity of nerves. The physiology of aging (especially reproductive aging) overlaps the physiology of stress.

Puberty and Aging

Many studies have demonstrated that puberty seems to trigger the mechanism of aging, and the idea of a "death hormone," located in the pituitary gland, has been suggested. Many degenerative diseases develop under the influence of excessive estrogen and cortisone (and as a result of the many metabolic changes which follow exposure to those hormones). Many of these diseases, especially those which appear after puberty and are more frequent in women, can be treated very effectively with the anti-estrogen and anti-stress hormones, such as progesterone.

Hans Selye pointed out that estrogen treatment mimics the first, "shock" phase of the stress reaction. An excess of estrogen (or any stressor) causes the pituitary to secrete prolactin and ACTH, and both of these hormones act on the ovaries to stop progesterone production, and contribute in many other ways to the process of atrophy. ACTH, of course, stimulates the secretion of cortisol. The removal of the pituitary obviously isn't a practical way to delay senescence, but protection against the "death hormones" can be achieved to some extent by altering the diet to minimize the effects of estrogen and cortisol.

Historical and demographic studies show that certain conditions affect the age at which puberty occurs. Ashley Montague has argued that we need more neoteny, that is, that we should try to preserve and to extend our youthful functions, because those are our most human qualities. If we can generalize from animal studies, delaying puberty could increase brain size and longevity, improve intelligence, decrease violence, and even make people physically more attractive (the "cute puppy" appearance is largely a matter of brain size in relation to the size

of the face and body). I think this will be the next step in human evolution. Just as nurturing, stimulation, and freedom promote improvement in the function and structure of the brain, cruelty and oppression act in the opposite direction. If puberty is delayed, then the importance of a culture which supports curiosity, exploration, play and sensuous pleasure seems obvious.

The physiological age of the parts of an organism depends in some way on the developmental stage of the whole organism. This contradicts the reductionists' idea that cells or tissues have an "intrinsic" lifespan which will cause them to deteriorate after a certain limited number of divisions. When pieces of breast tissue or skin were repeatedly transplanted from old animals to young animals of the same (syngeneic) strain, they were still in good condition after ten "life-times," and their survival was apparently limited only by the necessity of trimming them each time they were transferred, to make sure that no host tissue was transplanted with them. When old rats were grafted onto young rats, the old member of the pair lived to twice the expected age. Recently, young female mice were grafted onto old females, to investigate any hormonal factors in aging. The ovaries of the young animal appeared to age, and its production of progesterone decreased.

This kind of evidence (and the simple observation that the cells in skin and intestine undergo thousands of divisions in an individual's lifetime) strongly favors the idea that a systemic energy problem is involved in aging.

Energy and Evolution

When mammals and birds achieved the ability to sustain a high metabolic rate by keeping their bodies at a steady, fairly high, temperature, their "food chain," based on photosynthesis, consisted of organisms that generally lived at a lower temperature.

Sugars, proteins, and the saturated fats produced by warm organisms can be eaten by warm-blooded animals with no particular side-effects. Organisms that live at low temperatures, however, contain unsaturated fats. The consumption of large amounts of unsaturated fats lowers the metabolic rate, and accumulated unsaturated fats are susceptible to a spontaneous and toxic form of oxidation. (The toxic effects include damage to the respiratory apparatus and to the circulatory and immune

systems, increased rate of aging, and cancer.) These "low energy" foods in effect counteract the evolutionary achievement of a high metabolic rate. Several studies show that decreased consumption of unsaturated fats can delay puberty. Other studies show that an excess of unsaturated oil in the mother's diet can damage the development of the fetus's brain. The choice of foods which have less unsaturated fat tends to reinforce the achievements of evolution.

The seed oil industry has created a national phobia about the consumption of saturated fats and cholesterol, but there is no basis for the idea that those foods should be avoided. People with hypothyroidism are susceptible to heart disease, but their elevated blood cholesterol becomes normal when their thyroid function is restored. The body's highest concentration of cholesterol exists in the brain. The level of cholesterol in the blood strongly influences the production of the protective hormones, such as progesterone. The brain contains by far the body's highest concentration of these hormones.

In the winter and at night the respiratory energy producing system is damaged, and the protective hormones decline, and the harmful stress hormones increase. The immune system becomes less active, and mortality increases. Although ultraviolet light interacts with unsaturated fats in the skin to accelerate aging[1] and to produce cancer, ordinary visible light has several beneficial effects in animals. One effect is the "regeneration" of the enzyme SOD (superoxide dismutase), by causing its copper atom to be re-attached to the protein. Light also increases the activity of normal respiratory enzymes, and tends to normalize (or maximize) the production of hormones, including progesterone and thyroid. Animal migration to reproduce in regions with longer days is a way to benefit from this energy-promoting action of light. In adult birds, the increase of hormones in the spring causes the growth of new brain cells in the area that controls their singing. (In humans, the space inside the cranium keeps increasing into old age, and the amount of DNA in the brain also keeps increasing with age, but it has been assumed that such changes in adult brains result from an increase in the size of nerve cells, and an increase in the number of connective tissue cells, rather than from a continuing increase in the number of nerve cells.) I would expect an increase in the temperature of the earth, and increased use of artificial light (or migration) to lead to a prolongation of youth and the development of better brains.

Pollution

Besides the distortion of our food supply by the propaganda of the seed oil industry, there is increasing contamination of our food supply by heavy metals. Lead, for instance, has been spread everywhere, largely as a result of its use in leaded gasoline. Food additives are often contaminated with heavy metals from the sulfuric acid used in their manufacture. Practically everyone knows about the famous experiments in which food restriction increases the longevity of animals, as if eating were toxic. But removing toxic heavy metals from the food, without restricting the amount of food eaten, has had the same life-extending effect in experimental animals.

When estrogen is elevated (as at puberty, or in pregnancy, or with medical estrogen treatment) the absorption of iron is stimulated. During aging, the body's load of iron increases, especially if there is a deficiency of copper, and the body's content of copper decreases with age. Copper is an essential component of cytochrome oxidase, which has the crucial last position in the mitochondrial respiratory system. Copper is a component of the cytoplasmic SOD enzyme, which decreases with age. Ceruloplasmin, a major copper-containing protein, helps to keep iron in its safe oxidized form. Copper is involved in the production of melanin (itself an antioxidant) and elastin. The loss of melanin, elastin, and respiratory capacity, which is so characteristic of senescence, is also produced by excessive exposure to cortisol.

The protein, metallothionein, is rich in sulfhydryl groups, which bind heavy metals. It is assumed that this protein helps to detoxify and eliminate the toxic metals. This protein is induced by exposure to either a heavy metal or cortisol. A larger amount is produced in response to the combination of heavy metals and cortisol, than by either alone. Since copper, like the toxic metals cadmium, lead, mercury, and silver, reacts strongly with sulfhydryl groups, the body is likely to lose some copper when it is subjected to heavy metals or cortisol. I think this chronic loss of copper accounts for the obvious features of aging, such as loss of elasticity of the skin, lungs, and blood vessels, the depigmentation (demelanization) of skin, hair, and (in Parkinson's disease) substantia nigra, and for the decrease in respiratory capacity. The replacement of the copper by iron (and the loss of the copper-enzymes which protect against iron-catalyzed free radicals) probably accounts for the increased

formation of lipofuscin during aging. When copper-dependent mitochondrial respiration fails, lipofuscin has the ability to sustain energy production through glycolysis (by keeping the coenzyme NAD, nicotinamide adenine dinucleotide, relatively oxidized), so it is possible that lipofuscin is a primitive sort of defense against stress.

In animals, copper supplementation can restore natural color to white hair, and in one experiment, it increased longevity. At present, there isn't enough knowledge about the safety of different ways of administering supplemental copper. It can be toxic, and it oxidizes other nutrients. Besides choosing foods high in copper and low in iron and other heavy metals, other dietary choices which support thyroid function will tend to promote the retention of copper. Other dietary practices can minimize our production of cortisol (e.g., combining fruits and protein, since protein foods lower blood sugar and stimulate the secretion of cortisol).

Self-Regulation

Physical science provides a much richer picture of the qualities and potential of the material world than geneticists recognize. Even many physicists don't recognize the richness implied by the body of experimental results in their field. Many well-known physical scientists have had relatively holistic attitudes (e.g., J. C. Bose, Michael Polanyi, B. V. Deryagin, Frederick Soddy, V. I. Vernadsky). A rich view of physics has much to offer to biology. However, when I say that a holistic view of biology is open to using physics and chemistry, as well as ecology, history, and cosmology, to achieve an adequate understanding, I should mention that there is a school of weird (immaterial and "quantum" centered) physics which is presenting itself as a holistic world-view. To them, I think Einstein's remark still applies: "You believe in a dice-playing God and I in perfect laws in the world of things existing as real objects…" Elsewhere, Einstein observed that an object's fields amounted to an extension of its material substance, i.e., he preferred to materialize fields, rather than to dematerialize things, as some of the popular philosophers of physics do.

The orderly, epitaxial growth of crystals has been shown to occur across the thickness of a plastic film. A detailed study of this sort of long-range ordering process was made by Alexander Rothen. He was able to

demonstrate biologically specific adsorption at relatively great distances. Many other types of research in adsorption fields and long-range order make it clear that the interactions of atoms and molecules in cells needn't be governed by either direct contact or by random motion. When cell components are rearranged, they return to their normal position in relation to other components, revealing a great capacity for self-assembly or self-ordering.

The medical tradition of naturopathy recognizes a great capacity of the body for self-regulation and self-healing. I think these attitudes can be usefully expanded now, in the light of new knowledge about energy and structure. On the short time scale in which we think about the health of an individual, and on the transgenerational scale relating to having healthier, more intelligent children, and on the evolutionary time scale, I think we can see a tendency, not just to preserve homeostasis, but to move upward in energy and greater generality of structure and function. To provide more energy and scope for using it stimulates our ability to use energy meaningfully.

Some Implications

There is considerable flexibility in living organisms, and in higher and lower levels of organization, and we can see some of the ways in which structures of different complexity accommodate themselves to the surrounding conditions of energy and structure.

The conditions under which the brain develops, including gestational support and the later nutritional-hormonal-behavioral conditions, the degree of stress and stimulation, contribute to the brain's structural complexity and metabolic energy use, and to the organism's ability to cope successfully with the environment.

Vicious circles of physiology often stabilize an organism on a low energy level, which may involve disease or rapid aging.

The existence of a few systems of positive feedback (self stimulation), however, indicates that in our fundamental structure we are biased in an expansive, upward direction. Progesterone (and its precursors, pregnenolone and cholesterol) and thyroid hormones participate in some of the important positive feedback systems, involving energy production, stress resistance, and brain growth.

In therapy and in everyday living we can try to protect and promote our energy-producing and energy-using systems by seeking the stimulation, the conditions of light and temperature, and the foods that are appropriate for our evolutionary level.

Asthma and Metabisulfite

Townsend Letter for Doctors, June, 1986

An asthmatic friend of mine had several experiences of getting sicker when she was medicated for asthma. While hospitalized, her doctor insisted on giving her Alupent. After she left the hospital, she showed me the Alupent label and asked if I knew why it would make her so sick. The label listed metabisulfite as an ingredient. Since this substance is known to cause trouble in asthmatics, it is very odd to find it in an asthmatic drug.[1] I don't find metabisulfite listed as an ingredient of Alupent in the PDR or other drug manuals, and the physicians I have mentioned it to were surprised. Sudden death from "paradoxical bronchospasm" would not be paradoxical at all.

Biological Balance and Addictions

Townsend Letter for Doctors, June, 1991

A good salesman knows how to get onto waves of rising enthusiasm. Intuitively, politicians, cult leaders, and scientists use the same process. The quick rewards of joining a rising tide reinforce the conformists' efforts, and thought needn't go much beyond "this must be true, because it works for me."

In the early 1950's, David Reisman discussed the idea of counter-cyclic activity in economics and culture, as an error-balancing technique. One of the simplest ways to evaluate the meaning of a cyclic process is to see what happens if it is damped or opposed, and to compare these results with an alternative amplification or reinforcement. The technique is useful biologically, as well as socially: pharmacologists have used the method for centuries, and theories of medicine are based on either damping or intensifying the wave-like processes.

Withdrawal from an addictive substance involves a physiological swing to a kind of "opposite pole," or nadir to the zenith of the drug's action. As no drug has just one effect, the deformation of physiology remaining when the drug is removed will not be a simple matter of a single "receptor" molecule. Physiology compensates continuously to maintain balanced functioning in the presence of a great variety of drug-like substances in our diet. When the diet is changed suddenly, eliminating alcohol or caffeine or other biologically active substances, our compensatory counter-cyclic adjustment is revealed.

The return to a physiologically balanced state requires many changes, and these occur at different rates. (The physiology involved in any organismic function consists of overlapping layers, each of which can work alone to some extent, and dysadaptation can affect the different layers—e.g., hormonal and neural—in different ways. And within a given regulatory "layer," such as the autonomic nervous system, there are various kinds of adaptive processes, including adjustment of energy charge, rate of "firing," thresholds, synthesis, and growth.)

It is important to think concretely about the processes in "recompensation" or restoration of balance. Some of the processes we should consider in relation to addiction are: tissue energy charge, metabolic detoxi-

cation and elimination, permeability and barrier functions, excitation-inhibition, and poorly compensated stress reactions.

Probably the biggest error in our popular culture of addiction is the idea that craving is triggered by the presence of the substance in the body, and that cleansing the substance from the body will stop the craving. This idea has become quite a cult, with ramifications into theories of obesity, allergy, sexual dependency, and violence. The common element in these widely promoted cultish systems is a distrust of the organism, a body-rejecting attitude that craving is necessarily bad, leading to a blurring of the difference between need and addiction. Cleansing the offending substance from the body to stop the craving suggests that the clean and pure person is without desires. Opposing this other-worldly doctrine is the fact that desires reflect needs, though seldom in a fully rational way. The fact that something makes you feel better, and that you feel worse when you stop using it, shouldn't be taken as evidence of its "addictiveness," but many people feel that way about thyroid hormone, coffee, vitamins, and even the most ordinary foods.

The fact that a taste of chocolate can provoke a wild lust for more chocolate, or that one cigarette renews the addiction, does not mean that the presence of chocolate or nicotine in the blood creates a craving. Rather, it is that an organism in an unstable state perceives the availability of something which promises to partially restore the desired stability. It is obvious that smoking cigarettes is not a good way to achieve the needed stability but this observation can't be generalized to the craving for potato chips, or coffee, or the multitude of other things that people often crave. There is often an easily discovered reason for cravings, and it is more fruitful to suspect that all cravings have a rational basis than to accept the Calvinist or Buddhist idea that desire itself is bad.

The availability of energy is central to our stable functioning, and the need for energy powerfully modifies our functioning. For example, as hunger increases, the brain's interpretive system changes in a way that causes increasingly unfamiliar things to be considered as possible food. The "spreading excitation" that leads to this extended search probably occurs in relation to needs other than hunger, and could lead to experimentation with drugs and to other activities that give some indirect satisfaction. Obsessive and compulsive patterns can sometimes be resolved by assisting the brain's energy metabolism, for example with a supplement of magnesium and thyroid.

But even hunger itself has such ramifications—protein deficiency, salt deficiency, hypoglycemia, elevated adrenalin and cortisol and growth hormone, for example—that a great variety of things could give partial satisfaction. Alcohol can make a powerful and positive contribution to nutrition by sparing protein, and by modifying nutrition-related hormones. (Although some of this work has been published in the *Journal of the American Medical Association*, the stigma attached to alcohol has prevented its adoption as a most useful drug/nutrient, even in terminal cancer patients, where its promotion of immunity could have great value. The abusive stigmatizing of useful substances is an example of unhealthily exaggerated social cycles.)

Behind alcoholism, it is common to find nutritional and endocrine problems, as well as emotional or situational problems. For example, a man who had been unhappy with his work and had struggled with "alcoholism" for 13 years, gave me the impression of someone lacking the basic hormone precursor, pregnenolone. A few minutes after he took 100 mg of pregnenolone, his depression and anxiety disappeared. Later, he said "that's the feeling I've been trying to get from alcohol, but it never worked." Pregnenolone, more powerfully than alcohol, lowers cortisol while stabilizing other systems. Its highest concentration in the body occurs in the brain, and its level declines sharply with aging; it very likely makes a large contribution to the adaptiveness and sense of well-being which are characteristic of healthy young individuals. In healthy young people or animals, additional pregnenolone has no detectable effect.

"Agitated depression," which is common in old age, is a common symptom of withdrawal from a variety of addictive substances. I suspect that agitated depression, or anxious depression, is a stress syndrome that makes ordinary adaptation difficult. The inability to cope with everyday problems often precedes experimentation with drugs. Low energy and high anxiety can lead a person to use either stimulants or sedatives, or both. Curing the initial problem should make withdrawal from many substances easier, though most of my experience relating to "addiction" has been with "alcoholism."

In 1979, I was thinking about steroid anesthesia, and decided to test whether the newly discovered "opiate receptors" were involved. Naloxone, the anti-opiate, didn't seem to block progesterone anesthesia, but I was still convinced that there was a connection. I think of progesterone as acting at a deeper or more general level, which could allow synergism

between opiates and progesterone, without naloxone's blocking the effect of progesterone.[†]

By chance, a musician who said he had been using heroin and alcohol for 40 years asked if I could help him sober up for an important job that was to begin in a few days. He said he had been continuously drunk for 6 weeks. He brought a quart of beer with him when he came to the house, and since we were having a holiday dinner, he had a chance to keep drinking wine when his beer was finished. At bedtime, I told him about my inconclusive experiments with progesterone, and described the other effects of the material, including its brain-quieting and anti-toxic, anti-stress effects. He took about 100 mg then (in vitamin E), and took the rest of the bottle to bed with him. Since he had serious cirrhosis of the liver, I explained that he should also take triiodothyronine, since this active form of the thyroid hormone is formed mainly in the liver, and I suggested that his nearly destroyed liver was probably making very little.

He got up around 8 o'clock the next morning, and was smiling and very happy looking. He said he had never had this experience before, of waking up without a hangover after heavy drinking. He had consumed so much of the progesterone that I repeatedly told him to be aware that it could interfere with his sexual function by blocking the effects of testosterone. He stayed alert and sober, and proceeded with his performances. He took about 30 g of progesterone in vitamin E over the next several months, and said his sexual functioning was perfectly normal. He took 50 μg of Cytomel morning and night, and his doctors gave him a few injections of magnesium. His doctors noticed that his liver was getting smaller, and about a year and a half later they said it was normal, without cirrhosis. (Since then other people have noticed similar effects on inflamed and enlarged livers, when taking progesterone with vitamin E and thyroid.)

Both progesterone and triiodothyronine have the function of increasing the tissue's energy supply, and in suitable doses can have a steadying, calming effect. While many people think of thyroid as a kind of stimulant, because it can cure the coma or lethargy of myxedema, this is a very misleading idea. In hypothyroidism, the brain exciting

[†] The systems which respond to valium and atropine are the places that I would want to look for clues to progesterone's effects on addiction.

hormones adrenalin, estrogen, and cortisol are usually elevated, and the nerve-muscle relaxant magnesium is low. Normal, deep sleep is rare in a hypothyroid person. The correct dose of triiodothyronine (the active thyroid hormone) with magnesium is a reliable treatment for insomnia, cramps, and anxiety, whether these symptoms are caused by fatigue, or aging, or alcohol withdrawal.

Aging, stress, and heavy consumption of alcohol increase the permeability of the intestine, causing increased absorption of microbial toxins. Laxatives, carrot fiber (not carrot juice), activated charcoal, and a small amount of sodium thiosulfate decrease the formation and absorption of toxins, increasing the organism's adaptive capacity. Belladonna can improve the bowel's function if there are spasms during drug withdrawal.

Camphor, adamantanamine (amantadine, Symmetrel), and "local" anesthetics taken systemically, can help in withdrawal from stimulants. The conventional (200 mg) dose of camphor and adamantanamine shouldn't be exceeded. (The hormones thyroid, progesterone and pregnenolone alone are sometimes enough.)

Smoking is probably the hardest addiction to break, but careful use of nicotine gum with belladonna (to block some of the circulatory effects of nicotine) can allow a person to avoid the worst toxins of the smoke while overcoming the behavioral habit of handling cigarettes, without having to simultaneously modify the chemical addiction. Caffeine[1] and vitamin A are very protective against cancers, including those induced by smoke. Progesterone and pregnenolone both have anti-toxic (or "catatoxic") effects, though their effects on nicotine craving are slight.

Our society's mystique about drugs makes it hard for people to rely on their own judgment and experience. If they want to try to feel better, aspirin, coffee, tobacco and alcohol are normally the only drugs they have to experiment with. Too many physicians think of "euphoria" as an undesirable side-effect of certain drugs, and are likely either to recommend stoicism, or to mechanically prescribe one of the standard mood altering drugs.

Ideally, a physician should view unhappiness and the feeling that life is getting too hard to handle, as a biological problem to be explored in cooperation with the patient. If circumstances are responsible, and can be changed, the biology will take care of itself.

The institutions and cults that have grown up around "treating addiction" are not so different from the cults and institutions (including

the pharmaceutical industry) that surround the use of drugs. Rationality and concern for the full range of real needs of people are likely to be ignored when stereotypes and ideologies can be used so profitably.

Dealing with addictions as having (directly or indirectly) to do with real needs can help to remove some of the unnecessary guilt and anxiety associated with addiction. This makes it easier to find out what is really needed to move toward a stable and balanced physiological state. As simple as it is to recognize addiction as a process of biological adaptation, there are many tricks for evaluating and facilitating the process, that can be discussed in more detail later.

Painters and musicians have sometimes said that they use alcohol or other drugs to help them find their "own way." Moving against the tide of the culture is an adaptive effort, and they find some neurological support in drugs. They are right in struggling against the current of imbecile conformity to find some creative truth, but there are better ways to sustain our energy and adaptive capacity. In some cases, good food and social fairness are enough to enliven people so that drugs are not attractive, and in other cases a more specific biochemical/energetic approach is needed.

Bowel Toxins Accelerate Aging Process

Townsend Letter for Doctors, February/March 1991

THE gerontologist, V. V. Frolkis, recently found that mice lived 43 % longer than animals on the standard diet when they periodically had activated charcoal added to their food. This is the clearest evidence I have seen that "bowel toxins" make a major contribution to the aging process. Although I think carrot fiber would have a similar effect, there might be important differences in the substances bound by wet cellulose and by microporous carbon. Analysis of the substances bound to the charcoal after it has been excreted should give us important new knowledge about aging. Besides endotoxin, I think the charcoal might protect against microbial estrogen and glucocorticoids, carbon monoxide, cyanide, and unsaturated oils. Absorption of heavy metals is probably decreased by all types of "fiber."

While Boganmoletz and Metchnikof saw the bowel toxins as the factor which drove the aging process, I see bowel toxins rather as a relatively late-acting factor that accelerates a process which develops for other reasons. Once our detoxifying mechanisms begin to fail, bowel toxins pass the bowel with relative ease, and rapidly destroy the remaining systems of defense and detoxification. The altered hormonal environment and weakened digestion of an aging organism create a new balance between the animal and the bowel flora, sometimes allowing the proliferation of more toxic flora. The accumulation of iron and other heavy metals, and of unsaturated fats, and the progressive loss of copper under the influence of the stress of darkness, are probably the central events in the process of aging.

Brain Aging

Townsend Letter for Doctors, August/September, 1992

Elie Mechnikov, like Pavlov, built a broad understanding of the nature of animals from a basic study of the process of nutrition. He believed that in the development of an individual, and in evolution, there is an early stage in which a division of labor occurs, with some cells being responsible for movement, and other cells (the amoeboid phagocytes) being responsible for ingesting and digesting food. The nutritional function of these latter cells was the basis for building and shaping tissues, and as the complexity of the organism increased, the phagocytes remained central in the preservation of the integrity of the organism.

Some examples will illustrate the ways in which phagocytic white blood cells preserve integrity. In a wound, white blood cells arrive quickly. Foreign matter, such as bacteria, is ingested and destroyed. If the object is too large to ingest, the cells adhere to it, and seal it off. Other white blood cells participate in healing, wound closing, and scar formation. Damaged or virus-infected cells of the organism, or cancer cells, or "old" red blood cells are destroyed and removed. Tissue remodeling—ranging from the tadpole's shrinking tail to the reshaping of bone by osteoclasts—is handled by this sort of cell. (That is, removal, replacement, and alteration of tissue are handled by this system.)

The energy available to the white cells, and the condition of the various tissue cells, govern the processes of phagocytosis, healing, and tissue remodeling. Thyroid hormone and body temperature are important factors governing the activity of white cells. The rate of movement of white cells through the tissue is strongly dependent upon temperature[1] (with the rate increasing with an increase in temperature), and they are generally tolerant of very high temperatures.[2] The conditions governing resorption of the tadpole's tail are probably relevant to how white blood cells function in mammals. Either cold or hypothyroidism tends to suppress or delay the phagocytic activity in the tadpole tail. With an adequate temperature and thyroid hormone, the cells selectively remove the oldest cells first, indicating that they recognize cellular age.

Although Mechnikov believed that the phagocytes were responsible for the atrophy of aging, he also believed that bacterial toxins from the intestine dominated the aging process.

Bacterial endotoxin inhibits mitochondrial respiration, and this respiration is needed for the intramitochondrial conversion of cholesterol into pregnenolone. With aging, pregnenolone and its derivatives, progesterone and DHEA, decline sharply. The brain, the organ with the highest concentration of those stabilizing substances, has many systems for adapting to their decreasing concentration, but the immune system is probably less able to compensate for those aging changes.

The combination of an extreme decrease in concentration of the protective steroids in the brain, and impaired function of the phagocytes, might account for some of the features of Alzheimer's disease. In this disease, microtubules accumulate within nerve cells and other nerve cells die, leaving tangles of their axons, including microtubules. These cells are not removed, as dead cells normally are. Subnormal temperature and hypothyroidism probably contribute to the inertia of the phagocytes. (In mammalian cells, microtubules dissolve at low temperatures, and are stable at higher temperatures. Phagocytosis seems to depend on a functional microtubule system within the white cells.)

But the reason for the nerve cell's death, and for the tangles of filaments within living cells, seems to be a metabolic problem of the nerve cells themselves. A few years ago, there was talk of a similarity between the "amyloid" deposits, and the blood protein, pre-albumin. Since that protein transports vitamin A and thyroxin, I wondered about the possible effects of a vitamin A deficiency. Vitamin A regulates lysosomes, and so a deficiency might promote the accumulation of intracellular debris. It is an antioxidant, and so a deficiency might tend to induce the stress-hypoxia proteins, and it is used massively in the synthesis of steroids (for example, progesterone supplementation spares vitamin A). But possibly most important is the "de-differentiation" that occurs in many cells in a vitamin A deficiency. In the skin and mucous membranes, a vitamin A deficiency acts like an excess of estrogen, to promote the formation of keratin.

Twenty years ago, English researchers found virus-like shapes in the brains of old people, and suggested that senility might be caused by a virus. Later, one of them found that aged brain tissue was antigeni-

cally similar to scrapie-infected brain tissue from a young animal, and antigenically distinct from healthy young tissue.[3]

In size and over-all structure, keratin filaments are similar to the scrapie particles, and to the filaments that accumulate in Alzheimer's disease. I think of keratin as a protein made by a cell which has lost the energy to make more functional proteins. Normally, keratinized cells are formed by rapid cell division at a body surface, where little energy is available. In chronic vitamin A deficiency, the keratin-forming cells divide more rapidly than normal. Dandruff and the moist white equivalent of dandruff on mucous membranes, leucoplakia, are promoted by a deficiency of vitamin A, or an excess of estrogen. Radiation often causes a similar hyperkeratosis, probably by destroying vitamin A, and, like estrogen, by creating a respiratory effect.

I suspect that the plaques in Alzheimer's disease are the brain's equivalent to the plaques of leucoplakia, or of dandruff, and that the overgrowth of the glial cells is the result of the same tendency of cells to divide rapidly, while the non-dividing neurons accumulate an excess of fibrous proteins that can't be degraded.

In degenerative diseases, the stress- and age-induced accumulation of iron and other mitochondria-toxic material (e.g., calcium, aluminum, and lipid peroxidation products including age-pigment) and the failure of detoxifying systems make therapy with ordinary nutritional supplements fairly ineffective. Direct supplementation of the various natural protective substances (or their analogues) in addition to the protective vitamins (especially E) and minerals (especially magnesium) is more appropriate.

The supplementation of pregnenolone, etc., will allow dietary vitamin A to be spared for other purposes, including regulation of mitosis, differentiation, and oxidation.

GABA-related metabolites, such as GHB, butyric acid, succinic acid, and the butyrobetaines, have multiple protective functions, including promotion of respiration and pregnenolone synthesis, regulating gene expression, and reducing damage from glucocorticoids.

DHEA seems to be involved in various regenerative processes, and a deficiency of it is prognostic of increased probability of death from various causes, including cancer, heart disease, and AIDS.

Progesterone has the special status of being an essential nerve growth factor, and generally blocks the catabolic actions of the glucocorticoids

and estrogen, thereby protecting all tissues, from brain cells to white blood cells.

Thyroid hormone protects against stress and supports normal differentiation.

Short and medium-chain saturated fatty acids provide a safe source of energy, as well as having hormone-like and adaptogenic effects. The short-chain saturated fatty acids are important in regulating bowel flora. Mechnikov's idea of altering the flora with cultured milk was on the right track, but much more needs to be done on bacterial nutrition and toxin formation.

Can Some "Anomalous" Structural Interactions Be Explained by an "Excitable Ether"?

Multidisciplinary Research, Volume 4, Number 44, 1976

FIRST, I want to indicate that I feel an ether theory is philosophically desirable, as an affirmation of rationality and causality beyond even that of the "traditionalist," geometrizing Einstein. Subjectivism in physics is being carried to extremes, and it is time to make physics again a strictly objective science.

Dudley and others have given some very interesting arguments for ways in which the neutrino sea could account for physical events which have traditionally been described in terms of special "fields" and "spontaneous events." I suspect that many of the "anomalies" that have accumulated in recent decades can be accounted for by a similar approach, though at present (for most purposes) I would feel just as comfortable with the phrase "previously unsuspected general process or medium of interaction" as with the concept "neutrino ether."

Lenin's definition of materialism was "the belief that there is something beyond what is presently known." This belief, and its opposite, define the two kinds of science that have been described by Kuhn as "normal science" and "revolutionary science," respectively. Since "normal science" doesn't postulate a world beyond what is known, it is always satisfied with any tolerably consistent set of descriptions. "Normal science" is possible only in a culture which is committed to the metaphysics of idealism, as opposed to a materialism as defined by Lenin. Lenin's materialism incorporates an assertion of the reality of time, an assertion of matter as our future, our potentiality. From the objectivity of time, this materialism (which is dielectical, developmental, historical or temporal) is committed to the reality of causality. It gives us an approach to physics which is utterly different from the idealistic tendencies of Jeans, Eddington, Schroedinger and others who assert that beyond our knowledge there is nothing.

Two Hindu physicists (Bandyopadhyay and Chaudhuri) have suggested a way in which time, by altering the neutrino sea, would be responsible for the cosmic red shift, and also for an altered gravitational constant. This is a concrete way in which the ether concept is made to affirm the objectivity of time, of causal sequence.

N. A. Kozyrev has successfully predicted numerous physical interactions by introducing

> *into theoretical mechanics the principle of causality and directivity of time. Such a mechanics can be called "causal" or "asymmetrical" mechanics.*

Kozyrev recognizes "the inadequacy of the knowledge of the essence the casual relationships," and so can be said to be systematizing a "previously unsuspected process or medium of interaction" which participates in all events, without specifying all its properties. His theory, which began with his studies of the internal structure of stars (1948, 1950) and stellar power, led him to accurately predict the cardioid asymmetry of Jupiter and Saturn (and Earth), the internal heat of Jupiter and earth's moon, and the red flares on the moon, and to account for the southward deflection of falling objects recorded by Hook (1680) and Reich (1832). He reports that the effect of the causal transmission of energy upon measuring devices such as clocks diminishes with the first power of the distance, and is not affected by shielding. Each of these points—effect on clocks, proportionality to the first power of distance, and passing through ordinary "shielding"—recalls a variety of other experiments which have seemed to involve unusual interactions, possibly involving a "medium of interaction." I will mention a few in the following pages.

Before the first world war, the "best" physicists thought they knew enough about the electrical nature of matter to reject as "ignorant" a theory of multi-layer adsorption which proposed a potential which could extend into space from the adsorbing surface, even through layers of adsorbed molecules. Thus, Einstein and Haber humiliated Michael Polanyi, rejected his data and ridiculed the notion of an "adsorption potential," almost causing Polanyi to give up his scientific career. About 15 years later, Polanyi and London collaborated to show how electronic fluctuations could account for the adsorption data obtained by Polanyi. Still, for another 15 years no one was willing to oppose the earlier, prestigious but ignorant opinion of Einstein and Haber to use and evaluate Polanyi's isotherm, which turned out to be the most widely useful adsorption isotherm, though Polanyi's never won prizes, as did Langmuir's mistaken theory. In fact, nearly thirty years later (or nearly 60 years after Polanyi's humiliation) I have questioned "experts" on the

subject, and found that almost all of them consider Polanyi's isotherm to be "wrong" and of no use, though they are also ignorant of the data relating to it.

After completing his thesis, Polanyi turned most of his attention to other problems in physics, but kept encountering data which seemed to indicate a kind of "smearing" of energy over considerable distances. For instance, while Max Born developed the theory of crystal lattices, again on the basis of merely local atomic forces, Polanyi was observing domains of some sort in crystals which seemed to involve delocalization of forces over distances of about 2 or 3 millimeters. He believed that he demonstrated that defects strengthened crystals:

> *I was deeply struck by the fact that every process that destroyed the ideal structure of crystals (and thus reduced the areas which could be regarded as single molecules) increased the resistance of crystalline materials. This seemed to confirm the principle by which I explained the low resistance of crystals to stress and to refute the rival theory...*
>
> *Polanyi's principle for understanding the strength of crystals was that the energy required for producing the new surface formed by breaking the crystal would have to be supplied from the stress stored up on either side of the future break, in an area extending two or three millimeters in both directions of it.*

Other experiments, involving plastic deformation, hardening crystals by wetting a surface, deformation hardening in one direction, and "recovery" of crystals, even a study of friction, all tended to support Polanyi's idea of the spatial extendedness or delocalizability of the energy involved in the solid state. In form, they seem similar to the adsorption potential which had been conceived without knowledge of "the electrical concept of interatomic forces." About the same time he found that the rate of reaction of chlorine was too fast to be accounted for by the ordinary reaction kinetics. Born described his results as requiring that energy just jump through empty space, as if that were impossible. It is now commonplace to use light to catalyze a reaction such as polymerization, even using chemiluminescence as the source, but the data

Polanyi obtained again seem to have been forgotten, in favor of a free-radical chain reaction explanation of the chlorine reaction. Polanyi now considers the adsorption potential to be explained by "resonance between the polarization of electronic systems," but I suspect that a common denominator of some of his work was an idea of an "excitable ether," which he in fact used in at least one publication.

The common "inverse square" relationship geometrically suggests that the force is being distributed as if on the surface of a sphere: so it would seem reasonable for forces extending from flat or concave sufaces (as opposed to points, or single ions) to decrease less rapidly with distance. This is apparently the case in the adsorption experiments of A. Rothen, in which antibodies are adsorbed out of solution by a layer of antigens spread on a thin layer of metal deposited on a glass slide. The effect depends on a certain crystalline structure in the metal, and is destroyed by subjecting the slide to a magnetic field parallel to the surface. In a recent publication (Biophys. J., 1974) Rothen reported that the slides were gradually inactivated during the day, unless shielded by about 3 cm to 5 cm of lead, but that they tended to be reactivated at night, by 1 cm of lead. Irradiation with gamma rays also prevented daytime inactivation. The period of inactivation and its maximum degree were greatest in the summer, corresponding to the position of the sun. Although he suggested comic rays as a possible cause of this diurnal change ("It is most intriguing that comic rays may be able to favor one configuration or the other depending on the penetrating power of the rays"), those rays are so nearly isotropic that such an effect is unlikely. Rothen's work has attracted little interest (except for a recent thief, who visited him to learn his method and then claimed to have developed it himself), over a period of about 35 years, and one story is that, after he had demonstrated that the effect could be transmitted through a plastic film, someone reported holes to exist in such films. The criticism was incompetent, not only because numerous layers of antibodies could be demonstrated, but because it has been shown microscopically that epitaxial growth of crystals can extend through a similar plastic film—for example, condensing sodium atoms in the pattern of the underlying quartz crystal. The ordering process in the two cases probably has some similarity.

The heavy shielding used to block Rothen's diurnal effect is reminiscent of the many studies done by Frank Brown, showing that organisms

in sealed and electrically shielded containers responded to events such as sunrise, sunset (and, I think, even moonrise), the arrival of the sun at the zenith, etc. For example, potatoes respire more intensely, clams or oysters open their shells when the tide would be high (if the tide could come as far as Indiana), etc. John Ott has made similar observations, for example that a mimosa plant (m. pudica) would continue to fold its leaves at right even though isolated in a cellar under a cement roof; another experiment showed that a plant would respond to sunset and sunrise under a few yards of earth, but that when taken down to a depth of hundreds of feet in a salt mine, the response stopped. Brown's studies show that biological clocks are set by external cues. Ott shows that the balance of radiation is crucial. A French microwave expert has used a complex combination of frequencies to stimulate animals' immune systems; his belief is apparently that a complex substance, the organism, is tuned to a complex frequency. Something of this sort seems to be involved in the highly specific resonance of Rothen's adsorption experiments.

Dror Sadeh mounted a cesium clock on a truck, and left another in Washington, D.C.; when he was a few hundred miles north of Washington a discrepancy between the clocks developed, in which one of them appeared to be "red-shifted," or slowed. The effect began at sunrise, and continued for a few hours each day; I think a similar but smaller shift occurred with moonrise. Anything which could affect the vibration rate of cesium might also be the (seemingly non-electromagnetic) cue by which organisms set their "clocks." Incidentally, the experiment in which a cesium clock was flown around the earth to test the relativistic "twin paradox" would have presented the clocks with a different number of sunrises, and so might be taken as a test of Sadeh's principle, rather than of relativity. Since Polanyi's adsorption potential is in effect condensing the molecules of a gas as they approach a surface, it is not hard to see a similarity between Rothen's adsorption of proteins onto a plane surface being modified in a diurnal rhythm, and Sadeh's diurnal change in the vibration of cesium molecules.

It is know that a lead "roof" of about an inch thickness produces an optimum shower of particles when hit by cosmic rays. Neutrinos are known to be produced in the process, so if there were a diurnal change in the energy state of an ether (consisting of a neutrino sea) which was affecting the various vibratory (resonant) processes, adsorp-

tive processes (also a kind of resonance, since Rothen's adsorption of antibodies demonstrates specificity), and biological processes, a lead roof might noticeably alter the average neutrino energy, possibly accounting for Rothen's effects. The Anderson-Dudley effect, in which a surface (or solid-state domains) can alter nuclear decay rates suggests an interaction of surfaces with an ether, a "sub-quantum medium" or sub-quantum mechanical level, to use Bohm's terms. If surfaces act on nuclei through such a medium, then it is appropriate to consider such a medium of interaction in other situations which involve surfaces, long-range order, cyclic effects, etc.

In an old monograph on cosmic rays (1942) an experiment is described in which pregnant rabbits abort when placed under a lead roof, and other experiments showed cancer growth rate was increased by the lead roof. In Sciencia Sinica (1964-66) a series of papers describes similar experiments, in which a similar lead roof produced different cancer rates at different elevations, with differences also being produced by varying the thickness of lead. Rothen's effect might also vary with altitude. Recently (1975) it was reported that, contrary to the previous belief that the greater "radiation" at high elevations would produce more cancer, the cancer rate declines with increased elevation, even for melanoma within Texas, according to a cancer geographer in that state.

Since many ether studies (e.g., Miller's large series of measurements of light velocity at different elevations) suggest that the ether density varies with altitude, it would be interesting to compare the effect of elevation (and shielding combinations, including deep mines) with the diurnal effects, on many biological and physical systems.

The medium of interaction in some cases could turn out to be a property of the matter itself, without invoking an ether. Intermediate states of matter, such as liquid crystals, interact with energy in previously unexpected ways. But while remaining open to many new kinds of explanations, we should keep in mind that the right kind of ether theory might be able to explain various anomalies, while unifying physical theory—and possibly also chemical and biological theory, as Kozyrev mentioned in connection with his theory. Such an ether theory would probably be extraordinarily fruitful in terms of new observations and new technologies.

Chronic Fatigue

Townsend Letter for Doctors, July, 1994

A good thing about science is that even dull-witted people can make real contributions to knowledge, by working carefully and methodically. Science tolerates (but doesn't require) quite a bit of stupidity. But I am inclined to think that education (or training) in science is heavily biased toward stupidity. It is through education that the achievements of science become part of our culture, and our culture influences the future directions science will take. So, both science and our culture would be better off if we would habitually ask whether the scientist's basic assumptions are justified, what alternative explanations had been considered, exactly what is meant by a specific word, and so on. Such questions almost always reveal the most embarrassing weaknesses in a position that "almost everyone agrees is correct." In biology and medicine, it seems that nearly everyone explains almost everything with a few interlocking ideas: DNA, membranes, membrane pumps, membrane receptors and receptors for the DNA, and ion channels. A belief in the explanatory power of these ideas can convert an observation that bacteria behave a little oddly when they are given ethyl alcohol, into a publishable speculation on the "molecular biology of membranes."

When the cells of fat, or depressed, or tired people are found to be in a low energy state, defective membranes, or membrane pumps or membrane receptors are often mentioned. Since phospholipids, which contain fatty acids of various degrees of unsaturation, are believed to be a major component of "the membranes," some people argue that eating more of the polyunsaturated fats will help to build new membranes, or to increase the "fluidity" of the membranes. If it is suggested that the cells should be producing more energy, some people suggest that, since the "mitochondrial membranes" are highly unsaturated, eating more of the polyunsaturated fats will help them to produce more energy.

A crucial enzyme in the mitochondrion is cytochrome oxidase, which reacts directly with oxygen, completing (or beginning) the process of chemical respiration. It is this enzyme (which is most sensitive to cyanide) which appears to be a "choke point" for energy production in various situations. Learning how to preserve and promote the activity

of this enzyme is an important issue for everything having to do with biological energy.

Mitochondria from animals which are fed a diet lacking the "essential" unsaturated fatty acids are more resistant to oxidation than the mitochondria from animals fed a standard diet containing unsaturated oils, but they also have very different in vitro swelling behavior. R. M. Johnson's investigations[1] suggested that "the swelling tendency in liver mitochondria…is associated with altered respiratory and/or phosphorylating mechanisms rather than with membrane alteration." Kunkel and Williams[2] found that the very high respiratory rate of animals fed a diet lacking polyunsaturated fats was caused primarily by a great increase in the activity of cytochrome oxidase, and that adding an "essential fatty acid" strong inhibited this enzyme's activity. (Other interesting observations were that "endogenous" respiration was low in the oil-deficient animals with a high metabolic rate, and aerobic glycolysis failed to produce energy, while anaerobic glycolysis was normal. Warburg emphasized the importance of aerobic glycolysis in cancer metabolism. Anaerobic glycolysis occurs in healthy cells. Aerobic glycolysis—the kind which is typical of cancer—being energetically idle in these animals might relate to the known freedom from cancer of animals which do not receive unsaturated fats.)

Cytochrome oxidase contains both iron and copper, and the copper component is apparently responsible for the enzyme's absorption of red light. The copper's function isn't understood, but it is suspected to be involved in regulating the efficiency of respiration. A protein called metallothionein, which is induced by cortisol or heavy metals, also binds copper, and might be one of the ways in which stress and heavy metal poisoning can accelerate the process of aging and degeneration.

The similarity of the effects of cyanide and polyunsaturated fats on respiration, and on cytochrome oxidase, suggests the possibility that the "essential" fatty acids might, like cyanide, form a complex with the copper ion. Unsaturated compounds, especially unsaturated phospholipids, can form strong chelation complexes with copper.

While thyroid supplementation produces increased activity of cytochrome oxidase, the avoidance of unsaturated oils would probably, to a great extent, make thyroid supplementation unnecessary to maintain a high rate of health-supporting mitochondrial respiration.

Pregnenolone often normalizes metabolism in a way that can make thyroid supplementation unnecessary, and part of its action is probably the result of stabilizing the mitochondria. Even cholesterol (which is converted to pregnenolone in the mitochondria) seems to have a stabilizing effect, since it inhibits oxidation of unsaturated fats.

B. L. Epel,[3] discusses the evidence showing that blue light inhibits respiration by inactivating cytochrome oxidase, and says "If it is conceded that this phenomenon is universal, it is then intuitively obvious that most organisms must possess a protective or active repair mechanism since sunlight appears to be directly detrimental to few organisms."

The many studies which show that red light promotes respiration probably explain the fact that the blue light in sunlight isn't very harmful, since the sun also contains red light, which would tend to reverse the damage done by the blue light. Since red light penetrates much more deeply into animal tissues than does blue or ultraviolet radiation, larger animals would be more strongly affected by the beneficial fractions of sunlight—the internal tissues receive only red light.

The winter sickness and stress of darkness that I have talked about so much are metabolic disturbances resulting from inefficient respiration, and involve fatigue, hypoglycemia with sugar cravings, and hormone imbalances which lead to nutritional problems, such as vitamin A deficiency.

Although healthy respiration is many times more efficient than glycolysis in producing usable energy, the combined effects of getting adequate red light and using butter and coconut oil instead of unsaturated oils will cause a great increase in energy consumption. People with a significant amount of fat in their body, who have in the past eaten foods containing vegetable oils, are likely to draw unsaturated fats out of storage, with toxic effects unless vitamin E, thyroid, and coconut oil are used protectively until tissue stores of unsaturated fats are depleted. (Typically, body stores of fat take four years to completely reflect the change to a different type of dietary fat.)

Coconut oil is rich in lauric acid, which is being discussed lately as an anti-viral agent. Lauric acid inhibits glycolysis, so coconut oil will tend to prevent hypoglycemia, while providing non-glycolytic calories directly to the respiratory system.

Milk and shrimp can contribute to mitochondrial respiratory efficiency, since milk has a low iron content, and shrimp are very rich in

copper. Iron is an important catalyst in the formation of free radicals, and copper is involved in protecting against iron, as well as in the function of cytochrome oxidase. (Even before Hartroft and Porta discussed, in 1967, the free-radical promoting activity of iron which forms "age-pigment," iron was known as a carcinogen or cancer promoter.[4,5])

Anemia can cause fatigue, and iron (like arsenic) tends to stimulate the formation of red blood cells, so many people advocate iron supplements for chronic fatigue. Although the immediate effect is to deliver more blood to the tissues, providing more energy, the long-range effects are not good, especially when iron is added to a diet containing significant amounts of the unsaturated fats. When anemia is caused by something other than iron deficiency (and it usually is), it is important to find the actual cause. Thyroid deficiency, estrogen excess, various vitamin deficiencies, protein deficiency, and various other mineral deficiencies should be considered.

Cold-Inactivated Enzymes as Metabolic Controls

Physiological Chemistry and Physics, Volume 3, September, 1971

THERE is now considerable evidence[1–10] that water is ordered, though not necessarily "bound," in the presence of macromolecules and in living cells. It has been suggested by A. Szent-Gyorgyi,[8,11] G. Ling,[5] and A. S. Troshin[12] that the state of water might exert control over metabolism, cell division, muscle contraction, etc. Some of the physical changes that we would expect to occur in ordered water are increased protonic conduction, stabilization of triplet states, stabilization of hydrated electrons, altered solubilities and ionic exchange, and weakened hydrophobic bonds. Anisotropic or ordered water (such as exists in narrow capillaries)[13] can have special properties, such as lowered vapor pressure, without being bound. Polanyi's adsorption isotherm, which assumes a potential acting through space, rather than only at the surface layer, seems to be an appropriate concept for understanding these long range effects.

It has been pointed out that lowered temperature weakens hydrophobic bonds, and that this may be the cause of cold-inactivation of certain enzymes.[14] The entropic contribution to exclusion of lipoids from the water phase would be similarly diminished in the highly ordered water of cells. Thus, we would expect the cold-inactivated enzymes, e.g., pyruvate carboxylase,[15] phosphorylase,[16] and estrogen dehydrogenase,[17] to be inactivated by the ordered environment of the resting cell, and to be activated by the relatively entropic state of cells in contraction,[18] division,[11] or anaerobiosis.[19] According to Drummond,[20] phosphorylase is in fact activated during electrically stimulated muscle contraction, without activation of phosphorylase kinase or increase in cyclic 3′,5′-AMP concentration.

If entropy changes in the cell water modify the activity of these enzymes, then this behavior of the proteins can be interpreted as an important control mechanism. Phosphorylase, and probably pyruvate carboxylase, would be homeostatic, or negative feedback controls, tending to provide energy in a state of low energy charge or physical activation. However, estrogen dehydrogenase, which uses estrogen as a coenzyme, may have an opposite effect, tending to destabilize the cell. If this is the case, another hormone system would be required to override the anti-

homeostatic effect of estrogen. Progesterone, which must be present with estrogen in a precise ratio (but at a much higher concentration) for reproductive success, may be the hormone with this function. This interpretation is consistent with observations that senescent animals may have high uterine metabolic rates,† high progesterone levels,[21] and that cancer tissue often responds to steroids; that is, any nonspecific irritation or insult that increased the entropy of cell water would promote the "estrogenic" state.

It seems significant that the known cold-inactivated enzymes are in important positions for the control of metabolism. It will be interesting to look for other cold-inactivated enzymes with this mechanism in mind. Also, it might be possible to learn something about cell water by studying these enzymes in vitro, their responses to surfaces, pressure, and other physical factors.

† Unpublished observations of this laboratory.

Comparison of Progesterone and Estrogen

Long Natural Health, October 16, 2014

Natural Progesterone (Thyroid Has Similar Effects)

- Decreases bleeding, prevents PMS
- Anti-tumor, anti-aging hormone. Shrinks fibroids of breast & uterus, cystic ovaries; effective in some types of cancers, such as cervical & breast cancers & estrogen-induced tumors.
- Inhibits prolactin (which stimulates breast milk production).
- Increases body supply of oxygen, prevents hypoxia.
- Cardioprotective.
- Improves circulation, brain structure and function, including memory.
- Mimics estrogen if needed or inhibits excess estrogen.
- Helps regulate edema.
- Increases intelligence of fetus by 35 points, protects against hypoglycemia by normalizing blood sugar.
- Sedative in large doses; stops seizures, regardless of the cause.
- Protects fetus from aborting (probably by keeping blood sugar up) and helps prevent toxemia of pregnancy.
- Decreases fat storage (oxidizes fat).
- Anti-aging to skin. Makes aged, atrophied skin thicker, more regular. Increases pigment cell size and branching, but doesn't cause young healthy skin to thicken. Thus, offsets darnage of catabolic hormones and replaces deficient hormones.
- Helps prevent and reverse bone loss, even in women on ERT.
- Inhibits fibrocystic breast disease by inhibiting estrogen or balancing estrogen/progesterone ratio.

Estrogen (Synthetic or Natural; Insulin Has Similar Effects)

- Excess estrogen (and decreased thyroid function) causes PMS (edema, excess bleeding, bloating, etc.).
- Excess estrogen (and decreased thyroid hormone) linked with breast/cervical cancer, tripled rate of gallbladder disease.
- Promotes production of prolactin (like cortisone). Thus, both, acting thru pituitary (increased prolactin) may promote osteoporosis, in spite of what you have been told or sold.
- Causes oxygen deprivation (hypoxia).
- Cardiotoxic, due to causing increased calcium deposition, increased hypoxia and increased blood clotting.
- Excess inhibits memory, causes migraines.
- Increases during stress and aging in both females and males.
- Causes edema.
- Must be balanced by progesterone to prevent toxic effects of hypoxia.
- Causes hot flashes, may cause cyclic seizures (during menses) when in excess relative to progesterone.
- Excess estrogen can cause abortion of fetus at ninth week, thus is abortifacient.
- Increases fat storage.
- Causes aging of skin, makes skin thinner (skin atrophy) extending to pigment cells, decreases cell size and eliminates dendritic branches. Also true of cortisone.
- Promotes osteoporosis by causing increased soft tissue deposition of calcium.
- Promotes breast cysts even in young children who eat meat, poultry and dairy products from animals treated with a synthetic estrogen.

Concerns About Progesterone Cream and Yam Extracts

Townsend Letter for Doctors, June, 1996

I notice that on page 68 of the April issue a word was added editorially to "Preserving the tissues," a chapter from my book on the menopause, which reversed my meaning. In the 7th and 8th lines, it should say "and other factors, especially progesterone and thyroid, allowed the organism to restore itself in ways that neutralized the cortisone response," but as printed it has me saying "estrogen…called up…progesterone and thyroid, and allowed the organism to restore itself…" My original wording expressed the opposition between estrogen and the restorative factors, but your alteration has me seeming to side with those who claim therapeutic benefits for estrogen.

In spite of Dr. Gaby's good comments on the "yam scam," I notice you publish an ad for a "yam extract cream." If progesterone is "a yam extract," then so is estrogen, and so are the anabolic steroids, the glucocorticoids, and the contraceptive steroids: Does the phrase "Mexican yam root extract" or "wild yam" honestly describe the contents of the product? Obviously not, because Dioscorea, wild yam root, has been in the National Formulary for many years, as a drug in itself, used to treat "bilious colic" and as a diuretic and expectorant. In the last several years I have spoken to people in the Portland and Seattle offices of the FDA about this, as well as with people involved in the production of the "yam" creams, and it seems clear to me that the FDA is either knowingly condoning this fraudulent labeling, or actively participating in it. While they fail to enforce their laws regarding honest labeling, they have told me that I (rather than those who mislabel the products, and who have falsely used my name in their advertising) appear to be the one violating the law by writing about progesterone and related substances while having patents on them. It is clear to me that it is the scientific information which offends them, not the illegal claims and mislabelings. It is only the latter over which they have jurisdiction, and it is there that they take no action.

If the yam-substance is applied to the skin, the saponins in it might be good for cleaning the skin (it was commonly used for washing clothes, shampooing, etc.), but they will have no hormone action. If the

"menopause creams" contain estrogen, they might have a systemic effect, but the studies of topical progesterone, by Papa and Kligman, showed that progesterone had a local effect, but no detectable systemic effect. This is because of its low solubility in ordinary oils. The progesterone-vitamin E combination, which I patented, is stably dissolved so that it can be absorbed by any route—transdermal, oral, rectal, or vaginal, but I have not licensed my patent to any of the companies such as Yamcon/Phillips Nutritionals or Pro-Gest/Transitions/Professional & Technical Services, which advertise creams for the treatment of menopause. Some creams contain progesterone, some creams contain vitamin E, some contain neither. The patented progesterone-in-vitamin E products are sold only in Eugene, Oregon.

The order in which ingredients are listed on the label must be in the order of their quantity in the product. Pro-Gest's advertisement claims that "For over 17 years, physicians have recommended Pro-Gest to their menopausal patients," but I participated in the design of some of the original progesterone lotions which were sold by Professional and Technical Services (while I was "President" of that corporation), and those early formulations (I still have copies of the various brand-name labels) essentially had no effective shelf life, because of their poor formulation; the progesterone was crystallized by the time it arrived from the factory. The composition of the various Professional & Technical Services products, at least according to their labels, has changed over the years. It is incorrect to say that Pro-Gest has existed for 17 years. One formulation, for example, showed a higher content of vitamin E than of progesterone, meaning that there was sufficient vitamin E to dissolve the progesterone, and thus to infringe my patent. When I pointed this out to MacFarland, he didn't want to pay me royalties, so he obligingly changed the formulation. "Cielo 2000" another of MacFarland's previous products, moved vitamin E far down on its label, meaning that its solvent action was very limited. My samples of Pro-Gest contain massive amounts of crystals, indicating that they didn't copy my patented composition.

A friend quoted one manufacturer of a progesterone cream, as saying, when she told him of my patent, "that's easy to get around." But a truthful label will say in a simple way whether or not it is violating my patent, by indicating the relative amounts of vitamin E and progesterone.

Lab analysis shows that the products licensed under my patent contain by far the largest amount of progesterone of any product tested, but the important point is that the progesterone is dissolved in vitamin E, and is completely available biologically. Crystalline progesterone isn't available transdermally, and when it is ingested, it is quickly metabolized by the bowel and the liver, into a derivative of progesterone, which has a certain biological activity, but which is chemically and biologically distinct from progesterone.

A small amount of any herbal saponin, such as those found in the Dioscorea yams, may be harmless, but larger amounts can be lethal, by causing hemolysis, and there is also some evidence that it can cause liver damage. The people in Mexico traditionally used the yam for washing clothes and for killing fish. Russell Marker, who created the steroid industry based on the Mexican yam, took a dose of saponin while working on a project in Mexico, and was seriously poisoned. His colleague, Norman Applezweig, said the next day that he looked as if he had "been hit by a truck," because he was covered by bruises resulting from the hemolytic action of the saponins.

Criticism and the Experts

Townsend Letter for Doctors, November, 1994

The present government of the U.S. is talking about reforming the educational system and the health care system. It is clear that the insurance companies and other components of the medical establishment aren't going to be inconvenienced by the reforms. Teachers, on the other hand, are increasingly being made the scapegoats for our national decline. I want to propose that an orientation toward results, rather than procedures, is the essential reform that we need in both health care and education.

The goals of both health care and education, I think, are to maximize abilities and pleasures, minimizing disabilities and displeasures. The World Health Organization has defined health in terms of decreasing dysadaptations, and improving our adaptation to our surroundings.

As Felix Meerson (described in my monograph "Resistance of the heart") has shown, the brain is the preferred organ of adaptation, because adaptation on the level of learning has no biological costs, in the sense of limiting our structure and function. As soon as we submit to a cultural stereotype or a textbook answer, we give up our creative capacity to adapt mentally, and begin to avoid problems, questions, and mysteries, because adaptation at any level other than creative imagination is a bodily stress; the acceptance of authority commits a person to wielding any authority they have, or helplessly adapting to the authority of others. Full health requires the responsible and creative use of the mind. This is why I think it is necessary to consider the reform of health care and education together, as a single project of cultural reform.

Certain things led me into a habit of doubting the experts. For example, in high school I had a state-certified biology teacher who refused to mention the word "evolution," an American history teacher who worshipped Hitler, and a "civics" teacher who told race jokes in class. Although it wasn't their apparent intention, they were contributing something to my education. In a graduate school seminar in American literature, I mentioned the relevance of social class to the work of some writer, and the professor interrupted to tell me that "there are no classes in the United States"; I explained that I didn't mean class or caste in the legally enforced sense that India and England have them, but social-

economic classes. At that, every student in the seminar joined with the professor to make it clear that I couldn't go on with my discussion if I had to refer to the "non-existent" social classes. That same summer term, I was looking for a job at a community college, and just a few hours' drive from the great university I found myself in the midst of horrifying unimaginable squalor. My fellow students had grown up in that region, and had to know about those areas. They helped to make me aware that there are academic fetish-ideas. Later I would find that the sciences were just as susceptible to academic fetishes, but that the humanities had the advantage of a tradition that emphasizes critical judgement; while the sciences base undergraduate education heavily on textbooks, the humanities emphasize study of original materials.

Over a period of several years, I enrolled as a graduate student in seven other departments, and learned to orient myself to what I perceived as a general academic psychosis, with variations to suit the subject matter; no department, from art to zoology, was free from the crazy authoritarianism, but a small percentage of individuals in any discipline seemed able to avoid the dogmatic frenzy. Once, in the late 1960s, I tried to communicate my perception to students at the University of Oregon. I organized a course called "Interdepartmental Perspectives on the Nature of Man." We invited the most highly-thought-of professors from ten departments to lecture on "their discipline's special contribution to understanding human nature." We had professors from the sciences, social science, philosophy and religion, rhetoric, and folklore. Six weeks into the course, we had heard six professors deliver one or two-hour lectures on the central importance of Noam Chomsky's generative grammar for understanding the nature of man. After the sixth lecture, one of the students took me aside and said "You're playing a trick on us, aren't you?" Since I had emphasized that the professors should talk about their department's special contribution, I wasn't responsible for the embarrassing stereotypy of their lectures, but in fact, that student had understood my reason for organizing the class. In a later decade, "deconstructionism" might have been the specific content of the lectures, but the point would still be that the university curriculum consists largely of stylish, borderline-psychotic, garbage. (Seen from a certain viewpoint, that academic stuff seems neither trashy nor crazy, but rather elegant, noble, and relevant. You have to adopt that viewpoint to write an A

paper; you have to discard that viewpoint to do something useful. The desire for useful knowledge leads to an attitude of active criticism.)

The academic sciences and humanities are similar in their fear of responsibility for knowledge. Everyone marches in step, assigns the right textbooks, and holds the acceptable assumptions, so that they can keep their job. Ultimately (and frequently enough to keep people in line) the board of trustees exercises its power to herd the university faculty in the desired direction.

Because of my own experiences as a critical student, in 1959 or 1960 I conceived of having a college whose teachers and students were the trustees. (We called it Blake College, for William Blake.) Responsibility would be institutionalized, to some extent. To keep students from feeling that they were leaving the real world when they entered the college, I proposed that it should grant degrees based on "recognized achievement," and I specifically suggested that the BA degree should require a score above the 87th percentile on the Graduate Record Examination, since this score alone should be enough to gain admittance to any good graduate program. In fact, private universities generally recognized that a GRE score higher than that of 87% of the graduates from recognized U.S. colleges was a reasonable basis for graduate admission, but the state universities required that their applicants have degrees from "accredited institutions." (Our students all received their degrees, and their GRE scores averaged at the 95th percentile. A couple of our students had previously been ranked in the lowest 10% academically. A change of their feelings about knowledge changed their mental abilities.) The regional accrediting association told us that they would consider many factors, including the size of our endowment and whether we had a football team, and made it clear that they were a kind of mafia that wasn't sympathetic with our idea of requiring that every graduate have a high level of intellectual competence.

What this means is that competence is defined as a) enrolling in the institutions presently established by governmental authority; b) jumping through ten to forty hoops per year, for a certain number of years; the size and height of the hoops are set by the authorities in consultation with the experts; c) in certain cases, one or two flaming hoops may be required, to exalt the authority of the profession. Art Pearl, a professor of education, used to argue that students should be awarded their degrees when they enroll in college, since the degrees don't stand for any special

competence now, and the recognition of that would make people think about the actual qualifications needed for doing a job. If we compare education to the rites of initiation many cultures have, then symbolizing entry into adulthood with a college degree, earned by a feat of endurance, isn't so strange, but the ritual could be modified so that it didn't interfere with learning the things people really want to learn.

After people have proven their obedience/compliance, by years of expensive subservience, then they may be allowed to take certain licensing exams. By law, these tests are not sufficient evidence of competence, and only those who hold accredited professional degrees may take them. If people without degrees were allowed to take the licensing exams, it might be discovered that the endurance-training had a detrimental effect on the students' problem-solving abilities. Several years ago, it was discovered that students' IQs decreased with each additional year they spent in certain schools. In a study of graduate students, it was found that there was an inverse relationship between their academic standing and their distance from the mean IQ, in either direction, that is, the mean IQ is excellent academically.

If we are concerned with what people know and are able to do, then we can find ways to help them develop the knowledge and ability that they want. However if that goal is a fraud, and we really want a nation of obedient, submissive, rigid and uncritical people who don't rock any boats, then we should just worry about keeping guns and drugs out of the schools (remember the math graduate student who murdered his professor?) and otherwise keep the educational system as it is, with emphasis on form, rather than outcome.

The idea of testing for competence (with varying degrees of generality, relating to specific tasks or ability to respond to novelty) would fundamentally change our educational institutions, but its influence would extend into the workplace. Many jobs would disappear if everyone's competency improved. In medicine, people talk about payment for keeping the patient well, instead of for alleviating or curing disease, but keeping the public healthy is going to require a major social effort to keep food, water, air, homes, travel and workplaces safe. If people become aware of their potential for creative adaptation and problem solving, the whole direction of the economy must change, because status and style-dependent consumption derive their importance from the absence of intrinsic interest in many of our activities.

Active criticism is an old idea that is close to "imaginative science." B. G. Niebuhr is considered to have founded German historiography with his concept of criticizing the source documents. Goethe used the phrase "tatige skepsis" (active doubt, constructive criticism) to describe Neibuhr's method. William Blake emphasized that criticism and imagination must be combined to correct error; doubt by itself is futile, imagination is vulnerable without organized and active criticism. More recently, Salvador Dali's concept of "critical paranoia" advocated the same intelligent use of the brain, to discover what is true, important, and interesting in ambiguous situations. Meerson, the investigator of stress physiology, speaks of adaptive culture as the first level of protection against harmful conditions.

For about 50 years, the concept "psychosomatic" has been trivialized to mean "it's just imaginary." But now, the studies of the physiology of helplessness show that a seemingly small difference in experience and attitude can cause a very great difference in the ability to mobilize biological energy and various aspects of immunity, such as Natural Killer cell activity. There is now general agreement on the distinction between the demobilized state of helplessness and the state of active adaptation. If everyone could be "vaccinated" against helplessness, there would be a general improvement in health and ability to learn. But irrational institutions keep making helpless people. A culture which promoted a responsible, creative use of critical intelligence would minimize the experience of helplessness; and at the same time it would shift our adaptive habits upward, toward seeking reasonable imaginative solutions to problems that now are often perceived as stresses and threats.

After my experience at Blake College, in which the essence of the institution was to support the inclination of students and teachers toward being responsible for knowledge, I found that it was often possible to reinterpret institutional rules to create a similar temporary environment within the existing conventional universities.

The greatest impediment to doing this is probably the fear of unemployment; subscribing to the current academic idiocy, or the current cliche of the marketplace, is felt to be necessary to fit in. In questions of health and education our culture is at a critical point. Things could be reinstitutionalized to give all power to the drug, insurance and communication industries, or they could begin to be de-institutionalized to expand the scope for intelligent individual activity.

Art Pearl's suggestion that students be automatically granted degrees can be seen as the student's equivalent of tenure. If teachers were much more secure about their jobs, there wouldn't be so much pressure to conform. There are foolish and wicked teachers, and good and wise teachers. If students know there are objective standards of achievement, they won't be under the teachers' power; teachers will be challenged by the needs and curiosities of the students. Students will necessarily become conscious of the need to examine and question the source of information. Little kids naturally have that inclination, which is the inclination of good scientists and artists.

The Japanese have relatively high levels of achievement in education. They also invented crawl-in hotel "rooms," stuffers to pack people into subways, and snap-on apartments. Their achievement comes at the price of exhaustion, misery, and diseases of stress. They represent one of our potential futures. The other potential future takes into account our health and happiness, and defines health as having the capacity for creative mental adaptation.

Critiquing "Dr. McDaniel Responds" Letter

Townsend Letter for Doctors, August/September, 1996

PEOPLE have expressed concern to me about statements in the letter (June, 1996) from H. Reg McDaniel, Director of the Fisher Institute for Medical Research. Although it is headed "Dr. McDaniel Responds," the letter isn't responsive to Kenneth Sancier's questions, and even seems to further blur the "identity" issue that Sancier asked about. The editor describes McDaniel as a consultant for the company that markets "dioscorea." I don't know if that is accurate. Dozens, maybe hundreds, of people have asked me about a chart used in marketing Emprise products that indicates diosgenin is a precursor of DHEA. Although I can't imagine what enzymes might achieve that conversion, no one seems to want to say whether their products contain diosgenin or DHEA or yam tissue. If they contain yam tissue, then they should be discussing the issue of toxicity.

I don't doubt McDaniel's claim that the statements he makes "reflect the consensus of a research pharmacologist, biochemist, molecular biologist, gastroenterologist and gastrointestinal physiologist, as well as physicians who interpret scientific data…" While the editors of *JAMA* make similar claims about the authoritative nature of their publication, I noticed a completely idiotic statement about yams and steroids in that journal, indicating that the yams used by the steroid industry were the same as edible yams. (There are about 600 types of steroid-rich yam; a typical one looks like Bigfoot, weighs as much as 90 pounds, and is poisonous.)

McDaniel's group of specialists were asked to evaluate the set of articles cited in his letter. It would seem that neither McDaniel nor his professionals bothered to read the articles. Although none of McDaniels' sentences stands up to close scrutiny, let me comment on half of one of his sentences: [animals] "…were administered diosgenin and it was converted by the adrenals to pregnenolone and then to estrogen, (3) oral diosgenin reversed experimental diabetes, (4) oral diosgenin lowered blood cholesterol levels, (5) diosgenin has also shown the capacity to induce megakaryocytic differentiation of bone marrow stem cells in tissue culture; a demonstration of hormonal regulatory influence at the cellular level expressed free of other sources of endocrine influence…"

Far from saying that diosgenin is converted by the adrenals to pregnenolone and estrogen, Rao, et al., say it has not been ascertained whether it acts directly or by being metabolized. Their evidence argues against that, by "excluding any possibility of diosgenin having progesterone-like activity in mouse," since any pregnenolone produced would be far more likely to produce progesterone-like effects than estrogenic effects. A. Lipshutz's work made that clear.

Although I am not familiar with dioscoretine, and haven't read the paper by M. M. Iwu, et al., their abstract strongly suggests that it has nothing to do with diosgenin, because their hypoglycemic substance has an LD50 in mice of 0.58 g/kg, and diosgenin isn't likely to be that toxic. The paper by Iwu, et al., wasn't about "reversing diabetes," but only about the observation that dioscoretine lowered blood sugar after four hours in rabbits. Thousands of other seriously toxic substances can cause a sudden decrease in blood sugar.

McDaniel indicates that Malinow, et al., studied the effects of oral diosgenin on cholesterol, but, as their title says, they were examining digitonin, a toxin from a different family of plants. Since McDaniel brought up the subject by citing this digitonin study, I should mention that one of the effects seen by other researchers, with Dioscorea-derived compounds, is chronotropic heart stimulation, suggesting a parallel to digitalis.

Beneytout, et al., describe the HEL cells as a human erythroleukemia cell line, which isn't the same as McDaniel's description of them as "stem cells"; and they compare the effect of diosgenin to that of phorbol myristate acetate treatment, and say nothing that could be construed as "a demonstration of hormonal regulatory influence at the cellular level expressed free of other sources of endocrine influence." Phorbol myristate esters are recognized as potent co-carcinogens. Both diosgenin and PMA caused an increase in the number of cells containing 4 or more nuclei. Diosgenin, we might conclude, is as effective as PMA in promoting abnormal development in cancer cells. This would suggest that diosgenin is something to be avoided.

If McDaniels gets paid for mentioning DHEA, pregnenolone, diosgenin, and dioscorea on the same page, he has done his job. But the *Townsend Letter*'s important forum for uncensored dialogue is abused when someone uses it repeatedly for evasive verbiage and misstatement of fact.

Darkness, Water, Osteoporosis

Townsend Letter for Doctors, April, 1985

AROUND 1973, there was an interesting observation, in which eyes that had been burned by ultraviolet rays were treated with red or infra-red light, and the pain was relieved. Since I had been interested in solvated electrons, I wondered if this medical observation might involve a mechanism similar to the "bleaching" of trapped electrons in crystals or glass which has been colored by exposure to x-rays or gamma rays. Szent-Gyorgyi used to demonstrate that structured materials, e.g., ice, can stabilize excited states of electrons. He was curious about the existence of pigments inside organism, and suggested that they related to metabolic electrons, since he assumed that external light didn't reach these tissues.

In December, I drove in sunny weather all the way to Houston, and thought about light. Having read that the leaves of deciduous trees go into a negative protein balance (work by K. Thimann, U.C. Santa Cruz) as they age in the short days of autumn, I realized that the mechanism of aging that I have discussed in other newsletters could be general for all living things. Knowing that plants have "photo-respiration," that is, the respiratory production of usable energy during stimulation by light, I wondered if animals might have something similar, accounting for winter sickness, dark-stress, and aging itself.

Knowing that photosynthesis uses orange-red light (though other plant processes are stimulated by other colors), I wondered if that frequency also stimulated photo-respiration. Anyone who has held their hand over a bright light knows that red light does penetrate tissue. Pineal researchers planted a photoelectric cell in a sheep's brain, near the pineal gland, to see whether significant amounts of light reached that organ directly, and the device clearly indicated when the animal moved from shade to sunlight. So, when I got home I was thinking about how to design an experiment to test the direct effect of red light on tissue respiration, especially in the brain.

I had been home for a couple of days when a journal arrived in the mail, describing exactly the sort of experiment I needed to test the idea. Rats had a bright red laser beam shined on their heads for 15 minutes, and then the respiratory enzymes of the Krebs cycle was studied. The changes were consistent with enhanced respiration.[1] (The red laser has

been used for more than ten years to promote healing—references will be provided on request.)

So my present thought is that darkness does in some way "poison" respiration, and that light enhances it, possibly by the indirect mechanism of disposing of electrons that have leaked out of the usable-energy pathway.

When respiration is blocked, tissue takes up water. A simple illustration of this is the cornea—when contact lenses were very impermeable to oxygen, they caused severe corneal swelling. I think estrogen works by the same mechanism (and this explains why so many toxic substances are "estrogenic"). There was a doctrine that cells can move water only by moving sodium, so medical textbooks say that estrogen causes sodium retention; but it occurred to someone to actually measure the effects of estrogen on sodium and water, and they found that estrogen causes the fluids to become hypotonic, with a lower than normal sodium concentration.

Estrogen (like darkness and stress) promotes prolactin secretion. A previous newsletter discussed the experiments in which sodium suppressed prolactin secretion, while taking water without sodium stimulated it. So it seems likely that hypotonic (or sodium deficient) tissue fluids might be a common factor in the various situations which increase prolactin secretion.

In the salmon which swim up the Columbia river to spawn, the fresh water, which is very sodium deficient compared to the ocean, does stimulate the secretion of prolactin, and the prolactin is involved in their adaptation to the fresh water. The adaptation is very costly, though, because these fish undergo very rapid aging. Their bones are transformed in ways very similar to the bones of other animals in extreme old age; for example, the back humps and the jaw juts forward. (Since the fish vertebrae don't bear weight as those of a biped do, we shouldn't attribute the bending of the human spine in old age to "compression.")

Some recent studies have investigated prolactin's involvement in calcium disposition, and its contribution to osteoporosis. (Growth hormone is closely associated with prolactin,[2] and I mentioned in *Nutrition for Women* that there was some basis for thinking that estrogen might make osteoporosis worse, acting through the growth hormone. The editor of the *Yearbook of Endocrinology* (1984, 273) says "Consider, if

hyperprolactinemia leads to osteoporosis, and the administration of estrogens to postmenopausal women leads to hyperprolactinemia…")

Since it is established that excess prolactin does contribute to osteoporosis in humans, it seems reasonable to suppose that the dramatic increase in prolactin secretion when these animals enter fresh water would be the cause for the equally dramatic skeletal changes in the fish.

It is already known that excess calcium damages respiration and that calcium is associated with structural disruption of the mitochondria, and that tissues tend to calcify in aging. Inside cells, calcification begins in the mitochondria; outside cells, for example in blood vessel walls, the "ground substance" (a fine-textured component of connective tissue) can become calcified.

Hypotonic fluids are disruptive to life processes and structures. Even tissues which are not very cellular, such as cornea, joint cartilage, and the various "basement membranes" (which are rich in ground substance) can be damaged.

I suspect that we—fish and humans—have a simple way to protect ourselves from "hypotonicity," that is, from a deficiency of salts in our fluids. (There have been various observations in which one salt can substitute for another, at least to the extent of preventing an immediate disaster.) We carry with us a huge reservoir of minerals, our skeleton. In osmotic stress, it is better to lose bone material (and teeth) than to experience hypotonic disruption.

Undoubtedly the liberated calcium participates in adaptation in ways besides preventing swelling of the connective tissues, but I plan to examine the metabolic effects of calcium in future newsletters. (The bones also provide a large reservoir of sodium.)

Both prolactin and cortisone are secreted during stress (and in darkness), and both mobilize calcium. If calcium is so harmful to our energy producing system, why do the stress hormones dose us with it? I think this is largely explained by the generality of hypotonicity in stress, and by the convenience of the skeleton as a mineral reservoir. Selye illuminated estrogen by comparing it with the initial shock phase of the stress reaction (before adaptation begins), but the value of the comparison probably goes the other way, too. The essential element in stress is the inadequacy of energy to meet a challenge, and when energy is insufficient, water is taken up. (And some water is produced in the cell when oxygen is

electronically reduced; this "respiration" is not necessarily involved in energy production—even "age pigment" can convert oxygen into water.)

Selye found that various stresses caused connective tissue disease, such as scleroderma and arthritis. He didn't explain the mechanism. I think it is significant that women are much more susceptible to many connective tissue diseases than are men. For example, a recent Arthritis Foundation advertisement says that women are twice as likely as men to suffer from arthritis. Fibrositis, myositis, etc., are common in women. (I think the studies of adhesions being prevented by progesterone provide a good model for understanding connective tissue disease, and allergies or "auto-immune" diseases.[3]) When cartilage is soaked in distilled water (or hypotonic body fluids) it swells with tremendous pressure. The microscopic mesh of this connective tissue is rich in negatively ionized groups, which attract neutralizing positive ions, such as potassium and sodium. As the neutralizing ions are leached away, the negative ions repel each other, causing swelling and attracting more water. As positively charged calcium ions are made available from the bones, the swelling is blocked. Continued for a long time, this seems likely to lead to conditions such as arteriosclerosis and scleroderma.

Structural disruption of the mitochondria, as well as uncoupling phosphorylation from respiration, can be caused by cortisone. So it is interesting to see seasonal changes in the structure of the mitochondria, which are consistent with the ideas I have been talking about, that winter (and light deficiency in general) is what ages and kills us.[†]

Winter stress, elevating cortisone, could also be the reason for the non-adaptive depression of thyroid function in the winter. Many people have noticed an association between stress and periodontal disease. Gum disease is common in hypothyroidism, and bone loss is an important part of the periodontal disease. This same endocrine pattern, and not "postmenopausal estrogen deficiency," is the most likely explanation for osteoporosis in aging women.

When I was working on my hamster thesis, about 1971, I noticed an article which reported that aging women's urine revealed an increased ratio of estrogen to the 17-keto steroids. I think it was that article that

[†] A couple of other things to notice in regard to stress and season: in men, the sperm count, and in both sexes, the visibility of veins on the backs of hands when they are held at waist level.

started me thinking of aging generally in terms of a deficiency of anti-estrogens, including things such as DHEA.

DHEA has been studied in relation to osteoporosis. J. Hollo, et al.[4] reported that "Administration of norandrosterone decanoate or dehydroepiandrosterone to patients with menopausal osteoporosis resulted in normalization of the postload hypercalcemia. Calcium tolerance of menopausal patients without osteoporosis was not affected by dehydroepiandrosterone."

S. Brody, et al.[5] found significant positive correlations "between basal levels of DHAS and the DHA response to ACTH respectively, and trabecular bone mineral content of the distal forearm."

There was a study of prolonged DHEA treatment on rat bones, which I haven't found.[6]

I think rational therapy for osteoporosis would include thyroid, vitamin A, bright light, and either pregnenolone or a mixture of progesterone and DHEA, with a diet rich in protein and all the salts: calcium, magnesium, sodium, and potassium. A bias toward magnesium, rather than calcium, would protect against many conditions that occur in aging and stress.

Diagnosing Porphyria for Labor and Industries Claims

Townsend Letter for Doctors, April, 1996

POLYCYTHEMIA, scleroderma, and porphyria have several elements in common, but I have never seen a discussion of this. Although I have written about them before, my articles on these subjects haven't been widely published. When I saw all of these topics mentioned on the same page of the *Townsend Letter* (February/March 1996, page 98), it seemed that I should point out some of the features that make these a sort of family of disorders.

These are disorders of tissue respiration and energy production. Oxygen, estrogen, and iron have important roles in all of them. Men are more likely to have polycythemia, women are more likely to have scleroderma and some types of porphyria.

The Washington State Department of Labor and Industries' review of porphyria is representative of a bureaucratic approach to a disease in its exclusion of all of the publications that offer an opportunity to understand its mechanism in a general way; I think it is setting the stage for a pro-industry/anti-worker policy, in drawing its distinction between problems "triggered by" exogenous chemicals, and those "potentially caused by an exogenous chemical exposure." Scientifically, this sort of categorization is meaningless. I think it is reasonable to interpret any increase in porphyrin metabolism as possible evidence of work-related damage, which compromises the worker's adaptive capacity in many ways.

The document at one point approaches a recognition of the silliness of their approach: "It can be argued semantically that this was not a true 'porphyria,' because of the absence of hereditary enzyme deficiency; however, there is little question that this acquired 'porphyria-like' condition was highly morbid and also clinically indistinguishable from the inherited form of porphyria cutanea tarda."

Until the doctrine of significant genetic causation is subjected to the requirement of being obtained in "a rigorously designed, blinded and appropriately controlled manner," it would have to be considered "speculative and unestablished," if this document were coherent. (It appears that its authors drew their gun intending to cripple a branch of

alternative medicine, and shot their argument in the head.) The document's emphasis on defining the disease in terms of genetic deficiency gives the enterprise an overwhelmingly anecdotal quality, at best. Let us see the rigorous evidence on which the categorization is based.

The document bases its whole presentation on the presumed reality of "hereditary deficiency" of enzymes, and—probably for a reason—ignores the evidence for an enzyme excess, which can be so easily induced chemically or hormonally. Early steps in the porphyrin synthetic pathway are influenced by the availability of precursor substances and by the concentration of heme, and are extremely susceptible to environmental influences. The issue of the role of genes in the balance and organization of a complex enzyme system is so tenuous that the citizens of Washington should look into the state's manner of choosing its experts.

There is a long history of investigating the interactions of porphyria metabolism with estrogen,[1] with cancer,[2] with diet, and with excess iron. Estrogens are known to cause porphyria,[3] and to exacerbate the symptoms and biochemical disturbances in people with subclinical porphyria. Sometimes symptoms occur premenstrually, during the time of increased estrogen production—the term "ovulocyclic porphyria" has been in use for a long time. Puberty therefore increases the susceptibility to symptomatic episodes.

Porphyria synthesis begins at an important cross-over point of protein and carbohydrate metabolism. Succinyl CoA and amino levulinic acid can enter the Krebs cycle or the porphyria pathway. Protein catabolism feeds into these pathways. Increased protein catabolism or blockage of oxidative consumption of Krebs cycle fuel—for example by poisoning—makes these precursors available to enter the porphyrin pathway. Stress-induced oxidation of heme can eliminate feedback control, but the specific outcome can be modified in many ways.

Many serious long-range consequences of excess heme/porphyrin production and metabolism are currently being investigated, suggesting that a criterion of "twice the upper limit of normal" excretion, for recognizing that a problem exists, could allow far more serious problems to develop over time, that on the surface might seem unrelated to porphyria. In some cases of porphyria cutanea tarda, scleroderma-like hardening of skin occurs, but the ramifications of disturbed heme metabolism, resulting from exogenous factors, are far-reaching. For example, G.Y. Kennedy,

at the Cancer Research Laboratory, University of Sheffield, observed that a porphyrin shortened the time required to induce tumors, and porphyrin derivatives have been proposed to be "cancer hormones." The carbon monoxide produced in the breakdown of heme inhibits many enzymes.

The synthesis of heme/porphyrin, and the production of red blood cells, are stimulated by a lack of oxygen, or by toxins such as arsenic and iron, which cause oxidative stress. Emphysema, high elevation, sluggish circulation, and nocturnal breathing problems can cause enough oxygen deficiency to stimulate the formation of new red blood cells. Newborn babies often have polycythemia, as a result of limited prenatal oxygen supply.

At a certain point, the continued production of red blood cells can make the blood so viscous that this viscosity impairs circulation through capillaries, and creates a vicious circle, stimulating the formation of more red blood cells. Men are more likely than women to have polycythemia rubra vera, possibly because testosterone is anabolic to the bone marrow, and estrogen tends to slow blood cell formation (females of all species are relatively "anemic," compared to males, partly because their blood is more dilute), but I think the greater ability of men's marrow to respond proliferatively to hypoxia is influenced by many factors, including different nutritional requirements. (Estrogen tends to cause certain vitamin deficiencies and fluid retention.) Estrogen also significantly lowers body temperature, while testosterone tends to raise it, and the temperature of the bones is a powerful factor in forming new blood cells. But this isn't to suggest that the patient could benefit from increased estrogen, because estrogen consistently lowers the availability of oxygen.

Excess estrogen reduces the blood's oxygenation, for example by producing a barrier to oxygen diffusion in the lung. Hypothyroidism (which is causally related to an excess of estrogen) is known to predispose to emphysema, and treatment with thyroid hormone has often cured polycythemia vera, presumably by improving respiratory efficiency. Progesterone, which is known to stimulate the brain's respiratory control system, has also been used successfully to treat polycythemia, and in animal studies it corrects experimentally induced emphysema. (These treatments for polycythemia vera were mentioned about 30 years ago in *JAMA*, I think, though I don't mention that to give the observations credibility, just to show how generally distributed the information has

been). In Colorado, where the incidence of polycythemia is high, it was found that teaching men to get in the habit of breathing more deeply could solve the problem.

Although there has been a medical faction that liked to compare polycythemia with leukemia, to justify treatment with radiation or cytotoxic/carcinogenic chemotherapy (and following the treatment, the patients did get leukemia, confirming the doctors' belief in the connection between the two diseases), simply removing some blood and replacing it with fluid to bring the volume of red cells down to 45 % to 50 % improves exercise performance in polycythemia patients with chronic bronchitis, emphysema, overinflated lungs and hypoxia,[4] H.P. Ward, et al.[5] found that in some patients, lying down or sleeping could cause enough oxygen deficiency to increase red blood cell formation.

Increased viscosity of blood, and increased levels of adrenalin produced in response to hypoxia, cause increased risk of excessive blood clotting and thrombosis.

In my experience, clinical emphysema responds very well to pregnenolone, and for men, this has advantages over both progesterone and thyroid.

Impaired lung function is very common in scleroderma, even when there seems to be no evidence of lung involvement.[6]

Metal poisoning is often mentioned as a cause of both porphyria and scleroderma. It was probably this medical association that caused Hans Selye to create the animal model, in which the injection of iron contributed to the development of scleroderma.[7,8] Injected iron damages the liver,[9] and practically any kind of liver damage leads to estrogen excess and a chronic stress-like adaptive response.

Scleroderma used to be described as one of the "collagen diseases," because similar changes in blood vessels and connective tissues were seen in systemic lupus erythematosus, rheumatoid arthritis, polyarteritis, drug hypersensitivity, etc.[10]

Scleroderma (similar to several other "autoimmune" diseases) is much more common in women than in men, and animal models for several autoimmune diseases can be produced with estrogen treatment. Scleroderma often begins with edema of the extremities, Raynaud's phenomenon, and muscle weakness or "polymyositis," which are commonly seen in hypothyroidism/hyperestrogenism.

It is generally agreed that collagen is overproduced in scleroderma, and there is evidence of increased mucopolysaccharides in the skin.[11] This is reminiscent of hypothyroid myxedema; it has been suggested that mucopolysaccharides can act as a matrix for calcification.[12] Estrogen stimulates the formation of collagen, and increases its age-like properties, and progesterone opposes some of these pro-aging effects on connective tissues. Mere lack of oxygen stimulates collagen formation, and the opposing effects of estrogen and progesterone on tissue oxygenation can account for many of the tissue changes they produce.

Oxygen deprivation causes tissues to retain calcium (and iron), as does estrogen in many cases, being similar to aging in promoting cellular uptake of calcium. Since the porphyrins strongly bind metals, it has been suggested that they may have a role in mediating the deposition of metals in stressed tissues. Paroxysmal vasospasm occurs in about 90 % of scleroderma patients, and estrogen and adrenalin are known to synergize in producing vascular spasm; hypothyroidism normally involves elevations of both estrogen and adrenalin.

I have known women who developed scleroderma after beginning the use of estrogen, and who are reluctant to stop, because they had been told that estrogen would protect them from osteoporosis and heart disease. Men who have had a diagnosis of scleroderma have told me that with the use of thyroid and magnesium supplements, Epsom salts baths, and topical progesterone and vitamin E, their symptoms regressed.

Polymyositis sometimes leads to calcification, and this would be expected if the problem is related to mitochondrial respiration, as is now generally thought to be the case; thyroid and magnesium are often the factors needed to normalize mitochondria and prevent calcification.

Tumoral calcinosis is sometimes treated as a variant of scleroderma, but it is very different, and tends to be localized, without internal complications. I think many people get minor bony excrescences (bone spurs, osteophytes, exostoses, hyperostoses) during puberty, or at other times of hormone imbalance, which often disappear spontaneously, but this probably represents the same basic process, and would have very little to do with the severe oxygen deficiency states in which collagen synthesis is overstimulated. Growth hormone and prolactin imbalances have been suspected to have a role in some of these growths. (Both of these pituitary hormones are elevated by estrogen, and hypothyroidism

is often the cause.) Progesterone, thyroid, bromocriptine, and other things are available to normalize the pituitary, when that is responsible.

A weakened ability to oxidatively produce energy can lead to the maladaptive over-production of collagen, porphyrins, and red blood cells. Considered together, I think the mechanisms involved in these diseases argue for the importance of the nutritional-environmental approach to health care. The medical/bureaucratic preference for a "genetic" rationale for disease has overtones of "eugenics." When the state gets involved in genetics, eugenics, or medicine, they had better keep their own scientific standards at least as high as those they demand of the people they disagree with.

Education Against Knowledge

Townsend Letter for Doctors, December, 1990

> "There has to be a way to measure the quality and efficiency of a clinic just as there are ways to measure the same characteristics in a baseball pitcher."
>
> — Former Surg. Gen. C. E. Koop

YEARS ago, I was told by our state Superintendent of Public Instruction that "what students know has nothing to do with education." Since then I have occasionally wondered how many other people with responsibility for education have such a clear awareness of their social function. Many teachers and professors, who emphatically claim that education has something to do with knowledge, nevertheless will claim that there is no objective way to measure knowledge. Many of these teachers will base their students' grades on examinations, yet it is rare for a school or college to allow a student to take those same exams for full credit without enrolling in the course. Several professions require an examination to qualify for a license to practice, yet will administer the test only to people who have the appropriate degrees, as if the examination (which excludes a fair number of degree-holding applicants) were unable to exclude those with inadequate knowledge.

The National Endowment for the Humanities has done another study, this time showing that U.S. college seniors generally don't know very much. In their earlier study, they found that the average young person in the U.S. knew less about the world than people of the same age in Mexico, Italy, and all the other nations studied. I suppose this country spends at least 50 times as much on "education" as Mexico does. Dr. Koop has pointed out that "health care" in the U.S. is deteriorating, at the same time that its cost is increasing. Just as he proposes that medicine should adopt the serious and objective concern for performance that exists in baseball, I would propose the same for education.

The fear of objectivity in education and in the professions has to do with power. When a professor has secret criteria, his judgment can't be challenged. If his assumptions are unfounded, a student could

embarrass him by examining them. But, in a system which requires an accumulation of course-credits, good students quickly learn what is expected of them, and after a few years of learning not to question the assumptions of their "discipline," they are ready to become like their teacher.

Listening to an expert talk about a subject is often a good way to learn, but having your understanding judged by that same expert is very likely to inhibit a spirit of objective inquiry. Separating evaluation from instruction can make a tremendous difference in education. Students and teachers can disagree, and still have a sense of working together. Venerable dogmas and stylish trends can remain in the curriculum, but their mystique is likely to evaporate. Even textbooks are likely to change, because they are now designed to serve the teachers (who select them) rather than the students who use them. Whether the subject is music, or math, or language, or physics, textbooks are likely to be instruments for maintaining a mystique, rather than for directly communicating an understanding of the subject. Vague or fragmentary definitions of terms and symbols often make the subject seem more mysterious than it is.

I have seen teachers present in a day the material that they would normally teach in a semester or two, and it seemed that their students grasped the subject as a whole more clearly than the conventional students who attended dozens of lectures. This was in the early 1960s, at Blake College. This school has been described as a prototype for the experimental college movement of the 1960s, but my intention in creating it was to demonstrate what can happen when students are not required to conform to the cultishly departmentalized attitudes toward knowledge which dominate most schools and universities. Simply by letting the students know that professionalism was not sacred, they were allowed to see how easy it is to master the information which is normally so laboriously and pompously inculcated.

In a miniature way, my composition class at Montana State (1965–66) demonstrated the same process. The department "required" each instructor of freshman composition to grade according to department rules, subtracting so many points for misuse of a comma, or for using the wrong part of speech, or misspelling, etc., with the result that 50 % of the students failed the course. A few weeks into winter quarter, I decided that the procedure was just too pointless and degrading, for both students and teachers, and I told my classes that I was going to ignore their grammar

and spelling and punctuation when I decided on grades for their papers (though I still pointed out the conventional errors), but that I was going to grade on the content of what they said. If they communicated something of interest, they would get a good grade, but if they kept writing on the level of a grade-school child (which they did in an effort to keep the mechanics of writing simple, hoping to minimize errors) I would give them an F. They immediately started to write more interestingly and more complexly, and the errors in grammar dropped sharply, so that nearly all of them were passing even by the stupid departmental requirements. That spring, the university solicited grant applications for research projects to improve education, so I submitted a description of my class, with before-and-after examples of the student's writing, to demonstrate the dramatic improvement. Only one other person, out of the 40 teachers in the department, would talk about the idea of writing for content; I'm sure that the department chairman didn't forward my proposal to the committee that had solicited research proposals, since so many of the old-timers in the department were committed to the idea that the department's "standards" would be lowered if they didn't fail half of the freshmen. (Incidentally, the courses were called "Communication 121," etc., so I argued that it was proper to grade the students on the basis of communication, rather than form.) Since then, I have heard many people justify various "educational" ordeals, by saying "that would be like a child trying to learn to speak before learning the alphabet," or something to that effect. Their examples usually make exactly the point they oppose; for example, it would be a seriously distorted child who learned the alphabet before learning to speak. And much of our educational system, at various levels, is devoted to just that kind of distortion.

Unless the dogmatic power of "the authorities" is replaced by some objective standards of knowledge and skill, public knowledge will continue to deteriorate. Our interactions with the environment, with each other, and with other nations will continue to deteriorate. Public health and the standard of living will deteriorate, unless knowledge is treated with the same seriousness as the skill of athletes.

Education, Energy, and Ideology

Energy and Character, Volume 4, Number 2, 1973

GIVING students a place to be free, to find a self, to do some things they couldn't comfortably do elsewhere, is a useful thing that can be done by a free college, as well as by free schools for younger children. This function has (particularly in the early 1960s in America) been part of the process of creating a new culture "inside" the old one. The school had an insulating function, as well as a creative function.

But as the idea of "free colleges" became popular, around 1966, students started arriving at "free schools," such as Blake College, with preconceptions that had been shaped by filtering through mass media. Passivity, conforming to a certain role, was an alienated attitude that free schools had helped people overcome, but now it was an increasingly explicit expectation of new students. Instead of using freedom to overcome passivity, they identified passivity with freedom, and defended it. The role of "passive counter-culture rebel" was a fine capitalist invention. (Richard Alpert/Baba Ram Dass can be seen as the vanguard of the ruling class with his empty mysticism of passivity.)

In this setting, the creative function of the free colleges became increasingly important, but, as far as I know, Blake College is the only one that has consistently tried to make this clear. Over ten years ago, when the foundations that had denied support to us began funding parodies of our program in very conservative universities, we felt that the forms of experimental education were being disarmed and corrupted, so that exploitation could pass for innovation.

As a result, we have tried to emphasize that the beliefs that justify the form of the free college should also serve as guides in the integration and creation of knowledge. Just as Marx's perception of man's potential guided his understanding of alienation and exploitation and social development, it is a revolutionary body of knowledge that originally supported ideas of educational reform. We feel that our function is to contribute new knowledge and coherence to it, while disseminating it and using it in humane ways and as a tool of resistance against the alienated-alienating culture of the exploitive society.

In organization, we have de-emphasized the recruitment of students to support teachers, and have become a small group of self-supporting

collaborators, accepting students only on terms that will not contribute to further alienation.

Respect for the complexity and potentiality of matter is the foundation for this revolutionary body of knowledge. Use of the body as an instrument of discovery is an important part of our phenomenological method. Radical empiricism and dialectical materialism are among our commitments.

What Heraclitus, Blake, and Marx had in common was an intense honesty of method, and a perception of the tremendous potential of people who devote themselves to that kind of knowing. Many others including scientists such as W. F. Koch, M. Polanyi, and W. Reich, have extended this self-development into the natural world. Besides helping to expand our perceptions and knowledge, their great contribution has been to demonstrate a way of knowing and discovering that is simply human (and animal), but which contradicts all formalized doctrines of scientific method.

As I understand it, intuition is guided into even the subtlest and most complex aspects of the material world by the fact that subtle and complex aspects of matter and energy constitute consciousness, and that related and simple tendencies exist in both knower and known. Blake and Reich and S. Dali suggest that it is the erotic impulse that guides intuition, and prevents "paranoia" from being "uncritical" (Dali's terms). The materialist tradition in its richest form recognizes desire and the directionality of time; alienated or mechanistic materialism makes the absurd assumption of randomness whenever possible, as a complement to their ruling atomistic and deductive logic.

When consciousness is seen as a material and energetic model or image of the world, rather than as an alienated set of rules and symbols, it is more likely to function in a productive, unalienated way.

For us, science is important as an amplification of the human—both as perception and as function. The fact that stimulation can cause an animal's brain to grow—even in maturity—and can lead to inherited larger brains, suggests the significance of cultural evolution to the organism.

Perception is extended, just on the psychological level, by the discovery of new rules of interaction—what was random, now can be seen as ordered. This is vaguely analogous to the function of myth, except that this is both perceptual and interpretive, while myth is mainly just interpretive. A higher energy state of the brain allows awareness of a

broader span of the present, so that patterns which exist only or partly as a development through time can be perceived and used. Old theories of discovery could do no better than proposing a mysterious kind of luck in hypothesizing to account for the scientific success of some people. Mere intensity of animal perception is the whole trick. The difference from ordinary animal perception is its ability to dream new integrations when there is slight discordance of elements—i.e., it is more fluid, and able to be introverted.

An example of trying to amplify a function is the project of trying to find why some populations can fix enough breathed nitrogen to meet their protein needs, while in many populations protein starvation is very real. If a deficiency of vitamins or minerals is responsible, this would be an easy way of amplifying our "normal" function of fixing atmospheric nitrogen in our bodies for use in protein synthesis.

The emphasis put on the work function by Marx and Reich, the idea that real history begins when we can start realizing and creating ourselves through our work, combines an affirmation of time with a recognition of organismic energy.

Another perspective on the same idea is this: dreams affirm and shape life. The morphogenetic field of biological energy, which shapes growth and renewal, is known directly as consciousness; the dream cycle is also a voltage and resistance cycle, for example. G. A. Sacher has observed that brain mass correlates very well with longevity, and others have observed that the dream-activating function corresponds to brain size. Babies apparently dream very often and intensely. We feel that infancy is the direction of our evolution, biologically, and that the cultural stereotype of a child as one who doesn't work has to be overcome—kids are naturally high-generality problem solvers, wanting to contribute immediately to the world that has been reserved for adults.

Our invitation to others—students or teachers—is to come and play and dream with us, in our work of evolving ourselves and the culture. We are appropriating cultural achievements for ourselves, making them new and extending them, and looking for as many other peculiar cultural centers as we can find, because unique perspectives provide the richness for growing generality. We want our physics and our psychology and technology to incorporate the vision of the Mexican mountain villager and the Nepalese brahmin, because every village culture represents thousands of years of experience that will enrich our own village perspective,

"western civilization." The desirable high-generality integration will be many-levelled and rich, unlike most previous cultural syntheses.

European culture is flat and abstract; Mexican culture is many-levelled, but undergeneralized; China is the closest to our ideal of rich generality, especially its Taoist tradition with a dialectical awareness and emphasis on body, energy, and life.

The institution, or the person, that performs the "higher education" functions of discovery, communication, and criticism should have a vision of matter, organism, and society that serves as a guide to growth and liberation. Blake's statement, that unorganized innocence is an impossibility, should remind us that comprehensive understanding is necessary just for defense.

The dialectical idea of "criticism" has internal application, as well as being the proper interface with the static culture. The general way I use the concept is illustrated by some examples: Russian psychologists trained children to use the hand they weren't accustomed to, and found that their "characters" were improved, nervous heart conditions disappeared, etc. Alexandro Jodorowski used a theatrical form in which the actors present their "weaknesses" in dramatic form, and experience loss of some of their rigidities of character. Through his studies as a mime, Jodorowski discovered the neurological principles involved in the muscular rigidity and mechanical reflexes of a "decerebrate" animal, namely, that intensity of consciousness ("going to matter") and muscular differentiation and fluidity are closely related. Learning to visualize and move in patterns of unaccustomed complexity and sensitivity prepare the actor to present his new nature to the public.

Reich's emphasis on the complex interactions of muscles and awareness makes the same point. Our feeling at Blake College is that the human substance itself is involved in education, and that we work on ourselves as we work on our various projects.

"Culture" can be understood as the perceived limits of possibility. Class interests have been responsible for the "classical," static view in which man's capacities are limited in ways that justify exploitation. Other energy problems, e.g., diseases of age or poor nutrition, may harden the perceived limits of possibility. Just speaking the language of a sick culture is a threat to the naturally flexible perceptions, unless "innocence is organized" by a kind of paranoia that guards against limited desires and perceptions. Our work, of expanding our perceptions, and others',

requires a lot of different techniques, but the process can be described generally as the complexification of matter and consciousness through what Blake called "Mental War."

Education as Advertised in Napoleonic Times

The Suffolk Review, September, 1984

An etching by Gillray from a watercolour by an amateur, published 1st January 1809, undoubtedly gives an excellent clue as to the market at which many of the small educational advertisements in the *Ipswich Journal* were aimed.

These advertisements usually provide the following items of information: The name and address of the Principal(s), the Terms (financial and/or temporal), the Curriculum and Staff required. From this information, from cartoons and other sources an impression of education in the Napoleonic era can begin to be formed.

Many of the advertisements only run to two or three lines, but by superimposing information from a series inserted by the more regular customers we can sometimes get a glimpse of how these establishments thrived, what they taught and the fees they charged.

James Potter's school at Tuddenham, near Barton Mills had, in 1785, "27 Scholars and daily expected 2 Boarders." In 1792 James was advertising for an apprentice for three to five years and he expected a premium for providing this experience. Elsewhere in the same paper he announces the award of a silver pen to one of his pupils for writing. Both these practices are to be encountered in advertisements for several other schools.

Looking at James' letters we can see that his spelling did not match his penmanship—he "proberbaly" spelt as he spoke and that may have had its defects.[†] Dr. William King, son of one of Ipswich School's Masters, wrote about another man: "The name of our writing master was Harmer. He wrote a good hand himself and taught us to write in a steady firm hand. He took quantities of snuff. Young as we were we quizzed him for his 'h'; he always put it in and left it out in the wrong place, like Dr. Rose of Penang."[‡]

When James Potter died in 1806, Tuddenham School was advertised for sale by Auction by Robert Isaacson. Reading the list of Household Furniture is like a prospective parent being taken on a conducted tour

[†] James Potter's letter dated Feb. 1st, 1785 S.R.O.

[‡] MS Autobiography of William King M.A., M.D., F.R.C.S. (1786–1865) S.R.O. S/92/KIN/16284.

of the establishment and it is clear that the Potters lived in considerable comfort. The school must have been mainly self supporting in dairy and agricultural products—as indeed would have been generally expected in a country school:

TUDDENHAM SCHOOL

Near Barton Mills in the County of Suffolk

To be SOLD by AUCTION

By ROBERT ISAACSON

(Upon the premises)

On Thursday, July 24th and following days.

The valuable Household Furniture, Farming Implements, hay stover, growing crops of corn, and other effects, of the late Mr. JAMES POTTER, deceased. The Furniture comprises 19 sacken-bottom and bureau bedsteads, 16 well seasoned feather beds and bolsters, 38 blankets, 20 quilts and coverlets; pair of handsome mahogany dining tables, mahogany chairs with needlework seats and covers good Scotch carpet 4 yards square, wainscot dining and pillar tables, handsome Windsor, kitchen and chamber chairs, pier and dressing glasses, 7 desks and 11 forms; quantity of china, glass and earthenware, boilers, saucepans, kettles, &c; brewing and washing coppers, sound and sweet beer casks, mash and wort tubs, very excellent small barrel churn, and other dairy requisites, glass bottles, &c, &c.

The Farming Stock consists of 3 very excellent milch cows, weanel calf, 1 of the best and most useful mares in the neighbourhood, 7 years old, new tumbrel cart, and a half load ditto, nearly new, foot plough, stetch harrow, roll, excellent cart and plough, harness, sow in pig and three shoats; about 8 tons of rare stover, got up in the best condition, a quantity of manure, corn screen, bushel, chaff box, &c. 4 acres of oats, 1 1/2 acre of rye, half a load of rye straw, and a very neat taxed cart and harness, little worse for wear.

Catalogues to be had at the Hall, Barton Mills and Kentford; Bell, Mildenhall; Hope, Chippenham; Chequers, Worlington;

> *Griffin, Isleham; Green Dragon, Fordham; Red Lion, Newmarket; place of Sale; and of Mr R Isaacson, Auctioneer and Appraiser, Oak Farm, Cowlinge, near Newmarket. The sale to begin each day at 10 o'clock precisely.*

Some enterprising principals started an academy in one place and then, when it had established some reputation, opened another elsewhere, reaping the rewards from both. In 1800, Miss Beck and Miss Marsault announced their intention of opening an establishment for Young Ladies at Coddenham. They had both come from Mrs. Carter's seminary "at Lambeth near London." That this venture prospered can be seen from the announcement in 1806 that they were moving at Michaelmas to larger premises in Needham Market and we are left wondering whether their former assistants, Mrs. Howard and her daughter, continued to be as successful in running the Coddenham School. They were, for only a year later we find these good ladies advertising for an Assistant who "perfectly understands the English Language, Fancy Work, &c. None need apply who have not been in that capacity for some time." So it appears the school was thriving.

Cost of education in such seminaries varied considerably and depended on two main factors: age of pupils and type of tuition. In addition, "extras" could mount up rapidly—a financial trend not unknown in more modern times! As the war dragged on and the cost of living rose, so school fees increased. The Rev. T. Tennant, Curate of Claydon and Akenham, charged 12 to 18 guineas per annum in 1798[†] and 16 to 20 the following year.[‡] It is impossible to tell which increases were due to a school meeting with success and the proprietor feeling he could "get away" with an increase and which were genuinely due to the cost of living. Entrance fees were usually expected and varied from half a guinea to about five. At Mr. Tennant's school, the entrance fee was one guinea to the Master and five shillings for the Usher, one of the establishments for "Young Ladies" waived the entrance fee if one had already been paid to another school—this may well have proved an attraction when officers and their families for instance were moved from one garrison to another.

One advertisement for the Classical School at Beccles exemplifies the price of exclusiveness: "Where wine, tea and a single bed will be

[†] *Ipswich Journal*, January 1st, 1798.
[‡] *Ipswich Journal*, January 5th, 1799.

expected, an hundred guineas per annum."† More frequently, however, it is washing that is mentioned: "Washing not included," "Washing paid for separately," or even "Washing 12 shillings per annum." Since vacations were, on average, about a month at Christmas and a month at midsummer, this meant 12 shillings for 10 months washing.

Muriel Clegg writes that "the terms 'young ladies' and 'young gentlemen' conjure up notions of finishing schools, when in reality children of six to fourteen were being provided for."‡ The Preparatory School at Eye, run by Frances and Mary Reeve in 1801 proposed accepting "young Ladies and Gentlemen" aged three to five: Mrs. Cole of Ipswich took "12 Young Gentlemen" aged three to six to "prepare them for a gentleman's school," while Mrs. Batchelor at Wickham Market ran a preparatory school for "young Ladies under eight."

If we should feel this age range is exceptionally young, we should remember that the practice of parents separating from their offspring is different. In *A Portrait of Jane Austen* Lord David Cecil tells us that the Austen children "according to the custom of the time, were at first put out to nurse at neighbouring cottages,"[1, p. 29] though he makes it clear that in the Austen's case they were seen daily by their parents. Other families at that time may not have been so particular in this respect. Furthermore, "Young Gentlemen" frequently became Midshipmen in the Royal Navy at 12, as two of Jane Austen's brothers did, and so, indeed, did Horatio Nelson.

In any case these preparatory schools met with Dr. William King's approval. He was the son of the Rev John King, sometime Master of Ipswich School and had attended both Ipswich and Westminster in his own schooldays. Writing in the 1860's of his own early years, he comments, not without a justifiable degree of Victorian complacency, that:

> *One of the greatest improvements of the age is the preparatory classical schools, in which the young are separated from the old, so that they can neither be bullied, (nor) learn their vice in language or other things. The next great improvement is single beds for health, comfort and propriety. At Westminster I had*

† *Ipswich Journal*, January 8th, 1803.
‡ Muriel Clegg, *Suffolk Review*, Vol. 5 No. 2, p. 70.

> *to pay five guineas a year for a single bed. The Ipswich school had not arrived at that pitch of refinement. Most of the beds were double. With little boys this did not so much signify: but when a little boy of 8 or 9 was made to sleep with a big boy, he was liable to be bullied and dare not much complain. I believe my father afterwards thought this a great error in education. In those days I believe it (was usual) for grown up people to sleep two in a bed. Female servants often do it now: and I believe men servants often did it then. During the last 50 years we have improved in all kinds of comfort, health and propriety. Medical science has acted beneficially upon all departments of life, personal cleanliness, ventilation, fresh air, diet, sleeping apartments: to say nothing of water and sewage.*[†]

We cannot always tell from the advertisements whether the establishments were for boys or girls or whether day scholars were accepted as well as boarders, though the Rev. Tennant's entry for 1800 specifically states that "No day scholar permitted to associate" and the Rev. N. Redit of Grundisburgh advertised boarding accommodation for Young Gentlemen with "accommodation for Young Ladies in separate apartments."

It was on the point of boarding accommodation that Endowed or Charity Schools and Private Enterprise Establishments overlapped, for many of the charitable foundations allowed, not to say encouraged, the Master to augment his salary by accepting boarders, so that the word "Free" in a school's name frequently only applied to a minority of pupils. On the other hand, there were some foundations that stipulated that the Master should not be the holder of a benefice lest the duties should in any way conflict.

> *EDUCATION*
>
> *The FREE Grammar School at Botesdale, having lately been repaired and fitted up for the reception of boarders, will be opened the 23d inst., where young gentlemen are qualified for the University, the Professions, and Trade by the Rev. Wm. HEPWORTH. Terms twenty guineas per annum. Entrance One*

[†] MS Autobiography of William King M.A., M.D., F.R.C.S. (1786–1865) S.R.O. S/92/KIN/16284.

Guinea. N.B. French, Dancing and Drawing by proper Masters.[†]

Twenty guineas was a considerable amount of money in those days, but it appears to have been a fairly average charge. The basic fee for young ladies at this time was in many cases less, but whether when all the extras were added in, there was very much difference, is open to doubt.

The terms for the Dedham Grammar School at Christmas 1815 provide what is perhaps a representative example:

Dedham Grammar School

Xmas 1815

	£	s	d
Admission	0	0	0
Board & Tuition, Writing, Arithmetic, &c.	39	18	0
Washing	3	3	0
School Bill £	43	1	0
Books & Stationary	7	15	7
Allowances, &c. per Account			
Surgeon & Apocathary	2	13	0
Dancing Master	8	8	0
French Master			
Taylor	1	16	2
Shoemaker	1	13	2
Carpenter	0	12	2

School will open on 27 Jan 1816

Letter this 18 Dec 1816

Her Richardson

As for the subjects taught, one or two points should be made. The Dancing Master (nicknamed the "Hop Merchant" or "Caper Merchant" by irreverent youngsters[2, p. 62]), not only taught the steps of the minuet,

[†] *Ipswich Journal*, July 31st, 1792.

but also gave instruction in "deportment," a "vital accomplishment" in a "genteel" education, and, particularly in the early years of the period, also taught fencing in many cases.

The Writing Master, besides the loops and pot-hooks one might expect, also taught his pupils how to sharpen quills and generally care for the pens. This is clearly shown in advertisement inserted by G. Harmer (son of the snuff-taking Harmer referred to earlier) in 1812, offering pens for sale at prices from 4 to 10 shillings per 100 and guaranteeing satisfaction and offering due after-care. This was doubtless a profitable side-line, for a schoolmaster's was not a very lucrative vocation. In many cases it was only by combining the office of schoolmaster with those of parish clerk and sexton that the poor fellow could make both ends meet. "Writing in all the usual hands" appears frequently. In commercial courses this sometimes included shorthand, but more usually meant such scripts as Italic (favoured by the ladies), Large Court and Running Court, (used by diplomatic and legal people) and Coursive or Running Hand, which was what most people favoured. Though copy-books sometimes included such exotic scripts, as Syriac, Armenian, Muscovian and so on, it is extremely unlikely that even Hebrew would be seen in writing schools outside London, though Latin and Greek alphabets would be taught in all Grammar Schools.

Surveying skills were in great demand in the age of enclosures, canals and turnpikes. Many schools advertised surveying and some, especially in ports, also taught navigation. Sometimes these subjects were regarded as branches of "the Mathematics."

Drawing was an important accomplishment. Naval officers were encouraged to keep a sketch book of coastlines and harbour entries and Army officers frequently needed to draw pictures of fortifications. Besides this, a talent for portraiture or cutting a neat silhouette was a real acquisition in pre-camera times and botanical drawings featured in many scientific and travel books.

"Use of the Globes" (elementary Astronomy) was seen as a subject suitable for both sexes for "Terrestrial and celestial globes have always been prestige items, and were the basic furniture of the gentleman's library irrespective of whether he knew one end of a telescope from the other or whether the tropics were fashionable diseases or not."[3]

Besides the "Use of the Globes," young ladies were also instructed in, Geography and Fancy Work or Needlework intended to demonstrate

the various sorts of stitches (hence the Sampler)[4] but courses in Natural Philosophy (Science) were almost exclusively the perquisite of male education.

Schoolmasters were supposed to be licensed to teach, though no such requirement was expected of the ladies. "Failure resulted in loss and forfeiture of office. Such an offender was to be 'utterly disabled, and (ipso facto) deprived and the place void' as if such person so failing were naturally dead. 'For the first offence the penalty was three months imprisonment without bail, for the second, three months and a fine of £5.'"[5]

It appears from the Diocesan Registrar's seal fee book 1751–1810 that for the whole of this period the fee was 7s. 6d., for schoolmasters' licences. It is possible that other fees were charged, recorded elsewhere, but this was probably the main expense. However, there is considerable discrepancy between the lists of people who advertised in the *Ipswich Journal* and the list of names appearing in the Subscription Books, but there do not seem to be any cases where a schoolmaster was prosecuted for failing to have a licence.

Most of the Masterships of the Grammar Schools and many of the Endowed schools went to graduates, in East Anglia this usually meant Cambridge graduates, and the licences accordingly read "Licences to the (Free) Grammar School at…" Sometimes such a Mastership disqualified the recipient from holding a benefice. In the 1770s and 1780s licences frequently read "to keep an English School to teach Reading, Writing & Arithmetick," a little later "to Teach English Grammatically." In 1785 there was a spate of licences "to Teach School," in 1791, some licences read "to teach Grammar & the Catechism of the Church of England," and there is one very unusual example in 1794 when James Pyman was licenced "to teach & instruct Grammar, the Catechism of the Church of England & Other lawful & honest Documents" in the parish of Earl Stonham.

In an age when flogging was rife in the Army and Navy, it is not surprising that many schoolmasters made extensive use of corporal punishment, thus earning the nickname "flaybbttomists,"[6] (the Bishop's Register of Licences included "Curates, Schoolmasters, Surgeons, Midwives and Phlebotomists"), but "standing in the corner" and "Dunce's caps" were also used, as several pictures of those times show. On the other side of the scale, Silver Pens were awarded in a considerable num-

ber of these establishments as we have seen at James Potter's school (a tradition still maintained at the Skinners' School at Tonbridge), which dates back to its foundation in the 1560s, where the original cost was "two shillings and sixpence, two shillings, and twenty pence" for 1st, 2nd, and 3rd prizes respectively and "nowadays is of the order of £300 inclusive of engraving and presentation cases."†

What of the schoolmasters themselves? From the newspapers we can gain some insights into the hazards of the occupation of schoolmasters and of the dangers facing some pupils, of which these examples are illustrative: Edward Ford and John Dunthorne may or may not be typical, however:

> *Mrs. Ford very respectfully informs the Inhabitants of Ipswich and its neighbourhood, that some particular circumstances having compelled her husband to quit his school, whereby she is left with her family unprovided for, she is determined to continue it under the care of an able Master, having been so advised by some of her most respectable friends, who have kindly promised her their support…*
>
> *Mrs. Ford begs Leave to acknowledge most gratefully, the encouragement and support she has experienced from her friends, and having now opened the School under the care of a master every way qualified, hopes for the continuance of their favours. Terms for Boarders as usual. Day Scholars, 10s. 6d. per quarter.*

In November 1799 "The Commissioners in a commission of Bankrupt awarded against EDWARD FORD …schoolmaster, stationer, dealer and chapman" were meeting at the Bear & Crown to take the last examination of the Bankrupt.‡ Bankruptcy was very common at that time in all walks of life and Ford was not the only schoolmaster to experience it.

Whether this influenced John Bransby to leave teaching or not we shall probably never know, but in September of the same year he purchased "the HOUSE and SHOP now in possession of Mr. Forster,

† Information supplied by J. Parsons, Schools Clerk to the Governors of Tonbridge School.

‡ *Ipswich Journal*, July 27th, August 10th, November 16th, 1799.

bookseller, stationer and dealer in medicines, whom he is to succeed on Monday next" and "Returns thanks to those Friends who have entrusted him with the Education of their Children, and takes the liberty of recommending Mr. B. Strutt, his successor in the school."†

Whereupon John Bransby continued to flourish, thriving, no doubt, on the proceeds of medicines sold to troops returning from Walcheren, various surveying jobs and a pamphlet of observations and calculation on Hailey's Comet some ten years later. Whether Mr. Strutt thrived also we do not know.

In 1810 we read in both the *Ipswich Journal* and the *Suffolk Chronicle* of John Dunthorne, the schoolmaster at Dennington, being tried at the Quarter Sessions for "gross and indecent assaults upon several of his female pupils" being sentenced to pay a fine of 40s. to the King, for each offence, to be imprisoned for two years in the County Gaol and to stand in the pillory, in the market place, in Ipswich on the last Saturday of December of each year. Dunthorne appeared to be in his fifties. That he survived his punishment we know from the following entry in the *Ipswich Journal* in February, 1812:

> *Yesterday John Dunthorne, the schoolmaster of Dennington, was discharged from the County Gaol in this town having received a free pardon.*

† *Ipswich Journal*, September 28th, 1799.

Emprise Should Evaluate Conventional and Alternative Treatments Comparatively

Townsend Letter for Doctors, May, 1990

I hope you will be able to engage the Emprise people in a dialogue on the various approaches to cancer therapy. I think some of the people who seem so rabidly opposed to any therapy that deviates from the "standard" therapy of the moment are just misled by the claims that seem to be accepted by "all the respected authorities."

Several years ago there was a lot of publicity about the great improvement in the rate of cancer cures in recent decades, but someone pointed out that the death rate from cancer hadn't improved at all. About 20 years ago, Harry Rubin (an honest researcher in cancer-related matters) pointed out that if you aggressively hunt for cancer in any symptom-free 50 year-old person, you are likely to find it, since autopsies show identifiable cancer cells in everyone of that age. If refined techniques of screening for cancer (such as whole-body MRI) are developed, we can theoretically get extremely high "cure" rates without lowering the death rate at all.

Until recently, the American Cancer Society continued to base its propaganda on a weird procedure called "age standardizing on 1940," but they have stopped that. The post-war baby boom made the average population younger for a few decades, but now the birth-control pill is making the average population older. In this situation, the trick of comparing the death rate for childhood cancer in, for example, 1950, to the rate in 1986, would make it appear that childhood cancer was being defeated, just as the 1940 reference made it seem that the rate for old people has been improving.

Even the A.C.S. admits that radiation causes leukemia and other cancers, but they are apparently not interested in the effects of fallout from nuclear bomb tests on the leukemia death rate. Anyone who is sure that childhood cancer is being conquered by chemotherapy should consider Ernest Sternglass's discussion of the effects of radiation exposure on the incidence of miscarriages, congenital hypothyroidism and other birth defects, leukemia, brain cancer, and brain development. Since the 1963 agreement to stop atmospheric testing radiation exposure has been decreasing, and so I would expect a real decrease in the childhood

leukemia incidence. If you added a real decrease in incidence to the decreased percentage of children in the population, you could get a nice fat decrease in the deaths-per-100,000-population.

I have read widely in the conventional cancer literature, and I think the research is generally crummy, with a shockingly high proportion of what looks like deliberate distortion. It takes a long time to form a picture of what is going on in a particular area of research, unless you have some clues to begin with. A group like Emprise could do exactly the same thing for conventional therapies that they are doing for alternative therapies. This would make their work more credible.

Many people who were about to submit to a "standard" treatment have asked me for my opinion, and when I tell them they ought to read the research that their doctor feels is decisively in favor of the treatment, many of them decide not to proceed with that treatment. A few times I have given people reference to publications in the hospital library, and their doctors have refused to give them permission to use the library. I'm sure that an extensive and coherent compilation and evaluation of the scientific basis of conventional medicine would wreak at least a little havoc.

Energy, Entropy and Estrogens in Aging

Rejuvenation, Volume 13, Number 3-4, August, 1985

In my study of aging-changes in oxidative metabolism, around 1970 I began to notice parallels between aging and the effects of estrogens. Investigating further, it appeared that an energy deficit was the common factor, and that many harmful factors, including radiation and hypoxia, caused a similar pattern of changes. (Reference 1.)

A variety of biophysical methods (NMR and ESR of living tissue, whole-cell electrophoresis, the influence of electromagnetic fields on nerve cell latent periods, etc.) led me to interpret the biochemical changes occurring in various tissues in aging, hypoxia, and estrogen dominance as a coherent response of the cells to disorder resulting from an excess expenditure of energy.[1–3]

In 1971 I suggested that progesterone and related steroids would have anti-aging properties deriving from their effects on the structure of cell water and the energy charge of cell.[3,4]

The same pattern of estrogen dominance is seen in both sexes with aging, and in all species studied. The anti-estrogens, especially progesterone and dehydroepiandrosterone (DHEA) decline similarly with age in both sexes.

Since 1971, I have worked out the physiological implications of this approach, as I will describe briefly below, and I have tested the ideas in a wide variety of age-retaled conditions in humans, including (1) Alzheimer's disease and Parkinson's disease and other "senile" changes in nerve function, (2) a variety of senile degenerative skin changes (3) changes in the circulatory system including arrhythmia, hypertension, gangrene of the feet and putative "stroke," (4) changes in bones including osteoporosis and arthritis, and (5) changes in respiratory function, including emphysema-like changes appearing in old age.

Progesterone and other "anti-estrogens" have caused rapid and thorough recovery from many of the diseases which are widely considered to be the unavoidable consequences of aging. "Auto-immune" diseases have also been treated successfully, regardless of age.[5,6]

Many of the metabolic consequences of stress tend to create vicious circles of self-stimulating processes of decline, on both the cellular and

the systemic levels. The work of F. Z. Meyerson, especially his concept of the "calcium triad," contributes powerful support to this view.

On the cellular level, in aging and estrogen-dominance, Magnesium-ATP tends to be lost as calcium is retained in excess. The sodium-potassium-ATPase activity declines. Proteolysis increasingly dominates relative to protein synthesis. Repolarization of nerve, muscle, and secretory cell tends to be retarded, causing such diverse events as "elevated hypothalamis thresholds," coronary vasospasm, insomnia, hallucinations, delayed T-wave in the electrocardiogram, and leg cramps. Ammonia tends to appear in tissues in these states, as protein catabolism dominates.

On the systemic level in aging, estrogenic effects are evident: a tendency toward prolactinoma, toxic effects of prolactin on kidneys and other organs affecting water balance, disturbance of thyroid function, adrenal compensation or exhaustion, atrophy of muscle, skin, and other tissues. Prostate hypertrophy now appears to involve estrogen dominance, and to be reversible with progesterone treatment. Reduced sensitivity to CO_2 in the blood, and diminished gas diffusion in the lung also occur very frequently. Bowel function is altered by prolactin toxicity, and by other degenerative changes.

Since certain environmental events relate clearly to the patterned metabolic changes mentioned above, those events must be considered.

Animals of very different types migrate to higher latitudes for reproduction. At high latitudes the effect of the vernal increase of photoperiod becomes intensified. The light-induced hormonal changes which increase fertility also increase general vitality and decrease the problems associated with aging. The hormonal changes occuring in winter and at night aggravate degenerative processes and increase mortality in all of the species that have been studied, including humans, in spite of the use of artificial lights. Certain age-related conditions, especially osteoporosis and depression, can be alleviated with artificial illumination. It has been established that darkness is associated with diminished anti-estrogens, and with elevation of prolactin and cortisone. The normal diurnal cycle appears to be a factor in aging.

Loss of muscular tone in the bowel is associated with aging, and increases the likelihood of exposure to bacterial endotoxin and to bacterial anti-thyroid substances, and increases the antigen burden. Permeability of the bowel wall is increased by stress, and forms part of another vicious circle, promoting degenerative changes. These degenerative changes can

be reversed partly by treatment with hormones, but the altered bowel flora is a problem which requires further research.

Treatment with progesterone and other anti-estrogens has reversed a variety of age-related changes in humans and in experimental animals, and has extended the life-span of experimental animals.

A useful theory of aging should include three levels: cellular chemistry, physiology, and the relation of the organism to its environments. All of these levels can be involved in self-stimulating processes, stabilizing the organism at different levels of energy and entropy in such a way as to make degenerative changes appear to be irreversible. Nevertheless, intervention at certain points to reverse disorder is possible.

Projected research: I am investigating the biochemistry, and potential therapeutic use, of substances which seem to directly or indirectly promote cellular order, repolarization, and sensitivity to biological signals. To further rationalize chemical therapy for aging and its complications, I will try to determine the mechanisms by which extended photoperiods promote the desirable hormones. This will involve (1) examination of the effects of light on DHEA levels (2), the effects of photoperiod on intestinal flora, and (3) investigation of physical-chemical changes in light sensitive tissues during stimulation.

Energy, Structure, and Carbon Dioxide

A Realistic View of the Organism

Ray Peat's Newsletter, 2013

WHAT could be more important to understand than biological energy? Thought, growth, movement, every philosophical and practical issue involves the nature of biological energy. The question of biological energy is usually handled in the manner of the cosmologist who explained that the earth rests on the back of an elephant; when asked what the elephant stood on, the cosmologist replied that "it's elephants all the way down." Several decades ago, it was discovered that ATP mediates many processes in the energized cell, but there is still fundamental disagreement on the question of how ATP is synthesized, and how its energy is used to produce movement, to control the movement of water in cells and organs and to regulate the ionic balance of cells and fluids, and even why its absence produces rigor mortis.

When people actually try to examine the question of how the "high energy bond" of ATP can be transformed into usable energy, they sometimes find that it is easier to propose fundamental changes in the laws of physics than to find an explanation within ordinary physics and chemistry.[1] More often, biologists simply prefer not to go beyond the first or second elephant.

However, there is a way of looking at the nature of life that doesn't involve mythical beings. The writing of history, in science as in politics, is often an ad hoc convenience, usually done to achieve maximum self-justification. When Harry Truman announced that he had dropped an atomic bomb on "Hiroshima, a military base," he was revising, for a moment, the history and geography of Japan. Usually, fictional histories created by powerful institutions become part of a general culture, and are relatively permanent. "Scientific revolutions" and "paradigm shifts" are just tardy acknowledgments of the silliness of the ruling fiction. In the process of accepting a slightly more rational way of doing things, those who have reluctantly given up the old doctrine will look for ways to show that they were on the right track all the time, that all of the nonsense was necessary. They want to maintain the illusion that scientists are intelligent and rational, for the same reason politicians want to create the

illusion that they are just and wise. Television networks and newspapers agree that genocide is exactly where the president says it is, because they and the president have common interests; likewise, science journals and textbooks are there to protect the orthodox beliefs of institutionalized science, much more than to search for truth. For historical doctrinaire reasons, Aristotle's ideas and the culture that had been built up around them were practically eliminated from Anglo-American culture a few hundred years ago. In Aristotle's "formative principle," nature itself was creative and purposive, "teleological." His ideas, and the people who held similar ideas, were suppressed because of the dangerously democratic implications seen in them by the ruling classes. Since Ilya Prigogine's Nobel Prize, a false cultural history of "emergence" has been formulated, to derive the idea of the sudden appearance of order out of disorder, from the official anti-teleological (platonistic) rationalism that had seen change as a matter of random fluctuations in a time-reversible system, in which numbers are real and substance is unreal. In this new version of history, cybernetics is blended with neodarwinism, to explain order as something external to matter, and dependent on chance rather than purpose.

Since I was following N. A. Kozyrev's work (on stellar and planetary energy) from the late fifties through the sixties, I thought of volcanism as a process essentially equivalent to solar energy. Then, in 1968, I read Sidney Fox's experiments with heated amino acids, and saw that volcanism was a more appropriate energy than sunlight for driving the origin of life. In some of his experiments, Fox put nearly dry amino acids onto hot volcanic rocks, and when he added a little water, the amino acids polymerized spontaneously, and nonrandomly, into peptide chains; when these were put into water, they spontaneously formed microspheres, that looked like, and behaved very much like, bacteria. Fox saw his work as a validation of the principle that nature itself created higher order spontaneously.

Deep in the volcanic earth, or deep in the ocean, life would be protected from destructive ultraviolet radiation, whether or not the atmosphere contained enough oxygen/ozone to screen out that radiation. And thinking about volcanoes, I questioned the idea that life had to originate in the "reducing atmosphere" that was dogmatically required by the conventional protobiologists. Volcanoes emit water, carbon dioxide, and

a variety of strong oxidants. I think it is possible that atmospheric oxygen preceded green plants.

If Sidney Fox's spontaneously formed proteins and microspheres are similar to the original living cells, these forms of life appearing in volcanic seeps would have originated in an environment rich in carbon dioxide, and I have gradually come to imagine that the present ordinary respiration based on oxygen might have originated as an adaptation to an environment deficient in carbon dioxide, as life spread out from its volcanic origins.

The history linking volcanic life to contemporary sun-based life is still in doubt, but in outline we can think of the sun as a present energy source, and the chemistry of the earth as, relatively, an energy sink. Electrons activated by light energy from the sun give up that energy, as they move through various steps until they combine with oxygen. Energy flow, in this sense, is somewhat like the energy flow between the negative and the positive poles of a battery; ultimately, it produces heat, but in the process, it can produce work.

Life interposes itself between the "poles" of energy flow, and the flowing energy creates organization and structure, as it is dissipated into heat. Structures store some of the energy, and tend to increase in complexity, taking advantage of the flow of energy to create phase differences with expanded internal surfaces, like a finely mixed emulsion. Like a finely divided emulsion, the more highly energized the organism is, the stabler it is. It adapts to the available energy; energy is used in adaptation; the structures built with the energy are adaptive structures.

This idea of the development of organismic complexity as a response to conditions that are "far from equilibrium" was first clearly stated by V. I. Vernadsky, about 80 years ago, but now the idea is associated with Ilya Prigogine. The only difference is that Prigogine has inserted an element of indeterminacy, which seems to have ideological appeal for much of the academic world.

In Fox's production of the proteinoid microspheres, the ordered growth is a consequence of the properties of the substance in a permissive environment. The order is not imposed from the outside onto passive matter. When Darwin was a university student, he accepted Paley's doctrine of "Natural Theology," in which a watchmaker god inserted design into the material world. As he matured, he allowed for a certain Lamarckian intrinsic process of ordering, but he emphasized the role of

natural selection, in which the design was imposed by the environment, in the same way that animal or plant breeders use artificial selection to impose the traits they want. The neodarwinist movement "corrected" Darwin, putting all of the responsibility for the "design" of organisms onto the natural selection of strictly random variations. The cybernetic culture is having a strong influence on neodarwinism, and some of the new histories of science that are being written are trying to place the design process on the abstract mathematical level, rather than looking for it in the nature of substances. Devotees of "chaos theory" would entirely displace the designing principle from the material world. The meaning, and the effects, of this process of mathematizing neodarwinism are antagonistic to the facts demonstrated by Sidney Fox's experiments, and are tending to move research farther away from the creative nature of life.

Despite the present emphasis in "nonlinear dynamics" on random fluctuations and instabilities, the fact is that complex organisms, and finely mixed emulsions, are very stable, and the direction of their development is essentially determinate. Vernadsky described this fact as a law of evolution, that organisms and systems would tend toward the production of a high metabolic rate and large size. This means that evolution tends toward a maximum of energy use, a maximum of adaptive structures. The brain is the dominant organ of adaptation, and the evolutionary tendency toward "cephalization" is an illustration of Vernadsky's law.

The stability of the fine emulsion, or of the evolved organism (a person has greater homeostatic powers than a rat), involves the fact that, within a given range of available energy, the very complex structure has dissipated the energy within itself to a high degree. Every point of the system has come very close to being in equilibrium. It's a situation analogous to that of a road that climbs a mountain with a nearly infinite number of switchbacks—as the number of switchbacks tends toward a maximum, the slope of the road at any point tends toward a minimum.

Mammalian cells are smaller than frog cells; we are like a well homogenized emulsion, compared to animals with lower rates of metabolism. An unstimulated cell is practically in equilibrium with its environment. This is the "high energy resting state." Activity generates structure, but when a cell is inactive, it is stable and doesn't have to expend energy. This is exactly contrary to the doctrine in which a "cell membrane" maintains

the cell's organization by a constant expenditure of energy, running "pumps" to maintain differences in the ions and dissolved substances on the opposite sides of the membrane. In that doctrine, each cell, even at rest, is far from equilibrium; life is a struggle, and the cell must spend energy even to stay as it is. Gilbert Ling showed that the concept of membrane pumps to preserve the cell's order is both unnecessary and impossible. In the real organism, energy is spent to grow, to adapt, and to evolve, but not to merely persist.

If we understand Sidney Fox's spontaneously formed microspheres, I think we will get some insights into our own cells. For example, the microspheres have a remarkable uniformity of size, which they preserve even during growth, by dividing instead of simply enlarging. They tend to assemble into orderly chains, without coalescing with each other. They are stable in warm water, but dissolve in cold water. This indicates that the hydrophobic, "fatty" quality of the proteins, causes them to be expelled from the bulk water, forcing them into association with each other. Cold water has greater tolerance for fatty substances. The proteins, however, also contain regions that are water soluble, and when the proteins assemble into droplets, they continue to associate with a certain amount of water. This water is now "dissolved in the protein," in the sense that the properties of the protein are relatively dominant. (Bungenberg de Jong's studies of "complex coacervates" are still the best introduction to this subject.)

The modern practice of biochemists has been to extract soluble substances from cells, and to study them in dilute watery solutions, and then to believe that the things they observe in the test tube are the real properties of cells, of the "dilute solutions enclosed in a lipid membrane." If I hadn't had the experience of talking to dozens of biochemists who believed that no other kind of biochemistry was conceivable, I would find it hard to imagine that something like this could exist in a culture that defines itself as "scientific." Small particles have a large surface area in proportion to their mass. The balance, within the proteins, between hydrophilic and hydrophobic groups, will determine the proportion of surface area in contact with the bulk solvent water, relative to the mass of the microsphere droplet. More hydrophilic proteins will form smaller droplets, and at a certain point of hydrophilicity, will no longer form droplets. The temperature, by altering the structure of the water, inter-

acts with the hydrophilicity/hydrophobicity of the protein. Structures are generated as complex physical equilibria are achieved.

In our own cells, the microtubules, which are a part of the cell framework involved in cell division and movement, are dissolved at low temperatures, and are reformed when the temperature is raised. Some enzymes have this same temperature sensitivity. Since the water which is "dissolved in the proteins" of the cell is largely dominated by the proteins, its actions on microtubules and enzymes and other proteins will reflect both temperature and the influences of proteins and a variety of dissolved substances. Estrogen, for example, promotes the formation of microtubules, at a given temperature, as if it had made the water "wetter," or warmer.

When cells are stimulated, they adapt, with substance flowing into complexification until an approximate, appropriate equilibrium is reached. Stimulation is a need, and an opportunity, for adaptation and differentiation. If there is a need for adaptation, without the necessary substance and energy, the cell or organism will either deteriorate or withdraw. Polyunsaturated fats with inappropriate structure interfere with these adaptive flows of energy and substance in all of the known systems of cellular response. These exogenous substances suppress the respiratory energy system, the intercellular communication systems, and the intracellular response systems. Immunodeficiency, autoimmunity, inflammatory diseases, aging, cancer, heart disease, nervous diseases, and hormonal imbalances are produced when these fats interfere with the spontaneous self-regulatory processes of the organism.

When respiration is suppressed, the cell's production of carbon dioxide is suppressed. If we start with the best known example of carbon dioxide's effect on a protein, the Haldane-Bohr effect on hemoglobin, we will have a model for visualizing what happens to organisms in an environment that is poor in carbon dioxide, but rich in vegetable-derived unsaturated fats.

Carbon dioxide associates with protein in a variety of ways, but the best understood association is its reaction with an amino group, to form a carbamino group. In the presence of a large amount of carbon dioxide, the hemoglobin molecule changes its shape slightly, along with its electronic balance, in a way that favors the release of oxygen. The opposite happens in the presence of a high concentration of oxygen and a lower concentration of carbon dioxide. Other factors can modify the

effects of these gases on hemoglobin's shape, electronic properties, and its binding affinities. Wherever there is lysine or other free amino group (practically every protein and peptide), carbon dioxide can be expected to react with it to some degree, which will depend on other things in the environment. Lysine also reacts with sugars, so there is a competition between CO2 and glucose. In aging and diabetes, many proteins are altered by the inappropriate binding to sugars. There are enzymes which can remove sugars that have altered proteins, but these enzymes are inhibited by the presence of small fragments of starch molecules.

The absence of carbon dioxide bound to a protein is likely to have an effect on the protein's structure and function, but the presence of a relatively large sugar molecule, in a site normally occupied by carbon dioxide, will have drastic effects on the protein, including tending to solublize it, and to cause it to associate with its environment in other abnormal ways. In general, the presence or absence of carbon dioxide involves relatively quick and subtle changes in structure and function, analogous to the phosphorylation of proteins, but possibly competitive with it, while the presence and absence of sugars, as glycated or glycosylated proteins, tends to be relatively permanent, and to require enzymes to restore the original state. Carbon dioxide's regulatory effects have been studied in only a few enzymes and hormones, but there is enough evidence to show that its reactions with proteins and peptides constitute a major regulatory system.

The formation of carbon dioxide itself, from organic materials, has recently been demonstrated to provide the energy for synthesizing ATP.[2]

Around 1970, someone used a new technique that etched away the surface of a red blood cell, revealing an interior that was obviously highly structured, partitioned into orderly segments, but when I talked to biology professors, they still believed that a red blood cell was "just a bag of hemoglobin, enclosed in a lipid membrane." One of my biochemistry professors, who was smart enough to have opinions of his own, in private sarcastically referred to the "lipid bilayer membrane" as "the fat sandwich theory." But it would be several years before it became socially acceptable to talk about the cell's internal framework. Early in the century, before electron microscopes existed, a biologist had inserted tiny particles of carbon into cells under the microscope, and described their movement as they fell through the cytoplasm as resembling the movement of a pebble falling through a brush pile; it was obvious that

the clear cytoplasm was highly structured. The same biologist also rearranged the organelles within the cell, and demonstrated that they spontaneously returned to their normal positions. The cytoplasm can flow like a liquid, but it has some of the properties of a highly organized solid.

When I moved a microelectrode through a cell, using an apparatus that could move it forward or backward in very small increments, I found that the voltage fluctuated with the location in the cell, and that withdrawing or advancing the electrode, each location would show the same voltage as before, when the electrode returned. This meant that, even electrically, the cytoplasm was behaving as a solid, not as a liquid. According to the "membrane theory" of the cell, the liquid part of the cytoplasm has to have the same voltage in all of its parts. In that doctrine of a cell as "a drop of water containing dissolved molecules enclosed by a membrane," biochemists were required to think that enzyme-catalyzed reactions are governed by random collisions of the substances reacting with the enzymes, and that only a few properties of the solution, such as temperature, pH, and ionic strength, would have any influence on the behavior of the enzyme. Their doctrine seemed tenable to them, at the beginning of the 1970s, only because they had an essentially unscientific attitude that refused to consider the evidence, on the basis that valid evidence couldn't disagree with their position. In the case of hemoglobin, the idea that substances bound to the protein molecule could change its chemical and physical properties was accepted, and by analogy with that, additional "allosteric" (shape-changing) enzymes were beiing studied.

But, because of the commitments made to the "membrane enclosed cytoplasm" theory, the structural proteins were for a long time treated according to the rules established for enzyme chemistry—only local, random interactions were considered to govern their behavior.

In the 1950s, Gilbert Ling introduced a model of the cytoplasm that took account of its observable features. He called it the "Association-Induction" hypothesis. He proposed that substances such as ATP, hormones, and ions participated in cell physiology according to the ways that they associated with proteins and water, and that a powerfully adsorbed molecule, such as ATP, would influence the structural proteins in the cytoplasm as "cardinal adsorbants," altering the proteins' affinity for other adsorbed substances, such as potassium and sodium. The behavior of hemoglobin was a model for the behavior of the cytoplasm and its

components. Unfortunately, most biologists didn't even understand the role of adsorbants in hemoglobin's function, so practically no one bothered reading his work. The well-accepted fact of "backbone chemical shift" that results from something as simple as calcium binding to a protein is just another way of talking about the principle of association-induction. The actual chemical structure of the cytoplasmic framework in most types of cell had hardly been studied, and Ling concentrated on studies of the physiology of cells, treating the cytoplasm as an ensemble. Now that many cytoplasmic proteins are being studied in detail, the significance of his cell physiology can be seen more easily.

The "membrane" people like to talk about "ion channels" and "channel proteins," but they are simply describing fragmentary examples of the adsorption-induction process, in which strongly bound substances change the affinity of a protein for small ions and other associated substances. One of the effects of the membrane theory, and of studying enzymes dissolved in water, is that many biochemists got into the habit of thinking of proteins as water-loving materials; otherwise, why would they have to be enclosed by an oily membrane? But, in fact, proteins have a great affinity for fats. Fats are powerful regulatory substances. In excess, the wrong kind of fat associates with the cell framework, and alters that regulatory system, at the same time that it poisons enzymes and other functions.

Insoluble proteins tended to be discarded; sometimes they were called "membrane proteins"; when it turned out that the insoluble structural proteins often had "ATPase" functions, this enzyme came to be thought of as the "membrane pump." Even under ordinary assumptions about the way cells use ATP in their energy economy, Gilbert Ling showed that cells don't have the energetic capability of maintaining all of their gradients by "pumping" ions and other dissolved substances. But, the common idea that the phosphate bond in ATP is a very "high energy bond," with 14 kcal of energy, is an unfounded belief; in 1959, for example, Sidney Bernhard showed that a more realistic figure was around 4 kcal. But under relatively water free conditions, the bond forms spontaneously. One of the implications of this fact is that the control of water, the presence or absence of water, and the state of the water, is itself a matter of high-energy interactions. ATP does have a remarkably high energy of adsorption or binding to proteins, and this binding energy allows it to influence the protein's interactions with water. A very thin

layer of water between two objects can bind them together very tightly. The structures and movements in cells exist because of very specific interactions between large molecules, especially proteins, and the water which binds them and separates them. Both the water and the proteins are modified by the presence of carbon dioxide.

Two kinds of experiment show that the standard ideas about ATP and pumps have to be reconsidered. When muscles are stretched, they synthesize ATP;[3] this strongly suggests that its synthesis is a physica process, occurring in an environment in which water is inactive, allowing the reaction to be close to equilibrium. (In the heart, stretching has an anabolic effect.) In another experimental setup, the temperature is measured near the surface of a nerve; when the nerve is stimulated, the temperature rises momentarily above the starting temperature, but as the nerve recovers and repolarizes, the temperature falls below the ambient temperature. This "refrigeration," or heat absorption, isn't compatible with the activation of chemically powered "pumps" to restore the initial arrangement of ions, and it suggests something physically closer to the way that heat is emitted and absorbed by a rubber band when it is stretched and then relaxed. When heat production in a myelinated nerve is measured, the membrane theory would require that the heat production, like the electrical potential, should progress in a saltatory manner, jumping from one node to another, but the measurements showed that the heat production moves continuously along the nerve. This supports the idea that the bulk of the cytoplasm is undergoing a progressive phase transition.

Physically, all of these observations (which make no sense in the membrane theory) are compatible with a view of the cytoplasm as a cooperative molecular ensemble that is poised so that its alternative states are close to equilibrium, allowing it to spontaneously revert to its original state following a stimulus that changes its state slightly, or to cause systematic changes in chemical cycles which produce the substances, such as carbon dioxide and ATP, which tend to restore the original state. Nerve conduction, muscle contraction, and secretion are now recognized to involve the factors that cause "allosteric" shifts in molecular structure, association, and affinities. It is the myth of the cell as a "dilute solution organized by a membrane" that prevents the recognition that cell physiology consists primarily of such processes, coordinated into cooperative phase transitions. The recent discovery

that cell filaments form responsive systems extending from the cell's surface to the chromosomes makes it possible to see the process of genetic expression as an extension of this organized and unified system.

The standard doctrine about the structure of the membrane is that it is a lipid bilayer, meaning that an outer layer of fat (phospholipid) is arranged with its acidic water-soluble end turned outward toward the watery environment, and its fatty water-repellent tail turned inward, against the fatty tail of another layer of molecules, which has its acidic end turned inward, toward the supposedly watery cytoplasm. In support of this arrangement, an "oil loving" stain is applied to hardened cells (otherwise no membrane can be seen under the electron microscope), and a double line appears near the cell's surface. This is called the "lipid bilayer." However, since the theory says that the fatty parts of the two layers are pressed against each other, there is in the theory a continuous band of fat, separating two layers made up of the acidic heads of the molecules, and the theoretical structure of the "lipid bilayer" has no resemblance to the double line that is created by the stain. The material generally used to produce the image of a bilayer membrane is osmic acid, an oxidant; it wouldn't be expected to stain the layers of acidic heads of fat molecules. This might seem to be an embarrassing inconsistency, but apparently not to most scientists. After the electron microscope began making pictures of cells, it took some time to find the stain that would produce any membrane at all, and then it took about thirty years to learn to produce a "membrane" image that had a thickness that seemed appropriate for the theory. Considering the great effort required to produce a "membrane" image of the right size in the right location, they are willing to overlook the fact that the fat-loving stain hasn't quite found its way to the single band of fat between the acidic layers which their theory describes. Gilbert Ling described the boundary at the cell surface as a phase bouundary, of the sort that exists where two different materials meet, for example at an oil-water interface. When the two substances have different electrical-chemical properties, the forces between the phases move electrons and/or molecules near the surface into what is called an electric double- layer. Since stains have their own electrical and chemical properties, the stain molecules would be affected by the fields that produce an electric double-layer. Osmic acid would be expected to stain certain protein groups, including sulfhydryls and amines, which could be exposed in such an area of

strong fields. (Brain tissue that is deprived of oxygen stains diffusely with these "membrane" stains, suggesting that proteins are changing shape sufficiently to expose groups of this sort.) The forces between fat molecules, that allow them to form "hydrophobic bonds," are actually so weak that they should hardly be called "bonds," at least at normal temperatures. Fatty surfaces seem to seek each other out in a watery environment because water molecules bind so powerfully to each other that they tend to force out anything that doesn't bind to them. So, if we even consider the association between fat molecules as a "bond," it is the weakest bond that exists between any biological molecules. When a cell is attached to a surface, it can be torn to bits in trying to move it, without breaking its attachment to the surface. Obviously, it isn't attached to the surface by its "lipid bilayer membrane." The strength of a lipid bilayer would be limited by the extremely weak affinity of fat for fat; if you step on a sticky floor wearing tissue-paper slippers, your foot won't be ripped from your leg. A lipid bilayer has no more strength than the rainbow that forms on a puddle of water when a microscopic film of oil spreads over its surface. And the rainbow on the puddle is something that really exists.

Even though a cell's substance can flow, it has a cohesiveness that can greatly exceed that of ordinary watery solutions. The toughness of a steak isn't affected just by the extracellular connective tissue, as was once believed; the intracellular filamentous materials contribute greatly to its resistance.

Protein filaments can bind cells firmly to the materials that surround them, including other cells. Red blood cells normally float freely in a watery environment, but under some conditions they stack up into a rouleau, roll of coins, formation. The membrane theorists like to explain this pathological association in terms of ionic surface bonds, but experimentalists have pried the cells apart under the microscope, and photographed long extensible, apparently elastic, strands binding them together. The condition appears when the cells' energy is depleted, suggesting that the strands result from an alteration in the cells' internal framework. This kind of process would have practical application in the formation of a clot, producing strength and continuity that would be inconceivable if the red cell were "bags of hemoglobin enclosed in a lipid membrane."

If the cell's cytoplasm can be mechanically continuous with its environment, then the principle of allosterism, the conditionally responsive change of shape and affinities that is recognized in hemoglobin and some enzymes, has the potential for explaining the cell's ability to respond to its environment, and to alter that environment in a controlled way.

Filamentous, or other space-encompassing structures in effect are carriers and transmitters of fields of various kinds. A cooperative phase change (cooperativity means that a change which is slow to start will proceed quickly to completion once it gets started, because of interactions of its parts) can occur in a structure which has fluidity, so the signal transmitting function needn't be tied to mechanically fixed filaments. An ensemble of molecules can behave in a coherent manner resembling the behavior of hemoglobin. In fact, hemoglobin is a molecular ensemble which behaves cooperatively, as a functional unit, so there is nothing essentially novel in thinking about larger molecular ensembles making up the cytoplasm. Ions such as calcium are bound to oppositely charged ions, counter-ions, which are abundant on proteins. As the cell's state changes, calcium (and other) ions can be liberated from the binding proteins, and the momentarily high concentration of ions can serve to transmit an excited and activated state to other molecules, promoting enzyme activity, muscle contraction, nervous transmission, or other cell function. Not long ago, these movements of ions within the cell were explained in terms of membrane pumps and organelle membranes. Now, calcium-binding proteins and "channel proteins" have been dentified; the term "channel" derives from the idea that the impermeable membrane had to have pores for the entry and exit of ions and other substances. Supposedly "leakage" through those pores required pumps to compensate by moving substances in the opposite direction. At present, publications on ion channels are more than ten times as frequent as publications on their associated "membrane pumps." Many years ago, it was discovered that large numbers of sulfhydryl groups (a hydrogen bonded to a sulfur atom, which is often in the cysteine group of a protein) appeared during cell division. This represents a rapid and massive change in cell chemistry. The sulfhydryl group is ionizable, but in the late sixties and early seventies when the sulfhydryl shift still seemed important to biologists, there was no support for the idea that these groups could be involved in ion regulation, as part of Gilbert Ling's association-induction model of the cell. However, recently it has been

found that a "calcium channel protein" contains a cysteine group that ionizes during the molecule's change of state.[4]

Gradually, the idea of allosteric regulatory molecules that are altered by the reversible binding of regulatory substances has gained common acceptance, but the tendency is still to look for these signal receptors at the cell membrane and in association with the control of gene expression. But the cell filaments that make up the cytoskeleton are now known to form continuous systems from the cell surface, through the nuclear membrane, and into the vicinity of the chromosomes. These various filaments have "membrane-like" properties, allowing them to act at, and across, phase boundaries, but also making them sensitive to subtle changes in their environment, such as temperature, ionic balance, and the presence of fatty materials and materials combining various degrees of polarity in their structure; for example, the extremely toxic bacterial endotoxins are lipopolysaccharides, that derive their unique toxicity from the combination of fat and sugar in the same molecule.

For many years, the enzymes of glycolysis were the paradigm for the idea of random interactions between enzymes and their substrates, the materials they catalyze. They were thought to be the most random elements in a randomly organized system. Although it has been over ten years since Sidney Bernhard showed that these enzymes don't wait for their substrates to randomly diffuse into their active sites, this important fact is still generally ignored. (Others, from 1940 to 1998, have reported evidence that the enzymes of glycolysis are "bound to the cell framework.") The ordered behavior Bernhard demonstrated for these "most random" enzymes should be taken as a clue to the nature of other components of the cell.

Rather than having to transmit randomly received signals through random movements into the nucleus, the model of the cell that is implied by the work of Sidney Fox and Gilbert Ling is one in which "receptors" and "effectors" are distibuted throughout the cell substance. Rather than "feedback" of signals along channels of communication to processing centers, the processes of perception and response are distributed throughout a cooperative system, with the possiblity of response governing the process of judgment. There is intelligence in the system at every level, there is no coercion of stupid slave molecules. Fields, forms, associations, and movements all interact in a sensitive and responsive unity. At least they do in health.

In the process of an organism's development, the cell's form precedes its mature chemical functioning. The form depends on the internal framework, and that depends on the cell's contact with a specific kind of extracellular material. The matrix governs the basic pattern of gene expression, acting through the structural elements. In aging and stress, the matrix tends to deteriorate progressively. The matrix, being outside the cell, isn't constantly being renewed as the cell itself is, but it can be enzymically repaired, if the enzymes are not inhibited. Being located between the bloodstream and the metabolizing cells, it is necessarily exposed to all circulating environmental toxins.

There is a functional continuity between the extracellular matrix and the expression of genes.[5,6] This has been recognized for several decades by many researchers, but the doctrine of the cell membrane enclosing a watery solution has obstructed progress in this direction.

Some Implications

There is a chemical continuum from volcanic conditions to nerve cell structures and functions. The chemical precursors of life, ammonia, acetic acid, pyruvic acid, and amino acids are formed under volcanic conditions of high temperature and pressure. (Gunter Waächtershäuser, H. J. Morowitz, R. M. Hazen, and J. A. Brandes.) Under slightly milder conditions, amino acids spontaneously form proteins and self-replicating bacteria-like structures. (Sidney Fox, in the 1960s; Waächtershäuser[7] reported the synthesis of peptides, in a weirdly feeble parody of the work Fox did more than 30 years earlier.) Fox's spontaneously formed proteins improve nerve cell function—memory (in mice), and *in vitro* growth, survival (increased 250 %) and function, suggesting their functional similarity to ancient natural cellular proteins. Natural proteins become modified during development and stress, and these new primitive proteins might be interpreted by the cell as embryonic proteins, temporarily refreshing some cellular processes. The spontaneously formed protein structures are stable in warm water, and dissolve in cold water; microtubules and other fundamental cell components also "dissolve" when cooled. Formed in a hot environment, the synthetic proteins are biologically very compatible materials.

In this perspective, there is no point in which one has to insert an "assumption of randomness" into the process of cell formation or

functioning. The old idea of randomly arranged material, being ordered by the accumulation of random changes, was an idea that derived from the old concept of a watchmaker god inserting order into formless matter. In this more realistic perspective, the significant issue is what happens when disorder is introduced into the ordered cellular system. The introduction of disorder is a stimulus, a challenge to respond and to adapt. Excitation and assimilation, or excitotoxicity and degeneration, are two kinds of response to the introduction of disorder. Although the creation of order is a spontaneous tendency of the molecules, the introduction of disorder causes energetic changes that lead to the creation of a new order. The achievement of a new order builds on the old, emerges from the old, but contains the old order implicitly. The implicit presence of old structures accounts for the phenomena of memory, imprinting, transgenerational influences, and the recapitulation of phylogeny in development.

In the Randle effect (it's called the "Randle cycle," but there is no cycle), increasing the amount of fat in the bloodstream decreases the ability of cells to metabolize glucose; glucose tolerance decreases, as in diabetes, except that the response to fat is instantaneous.

Respiration decreases, mitochondria retain calcium, which tends to accumulate until it destroys the mitochondria. The calcium, when it is released from the mitochondria, causes excitation to increase. Stimulation without efficient energy production leads to proteolysis and apoptosis or other forms of cell death. Sugars replace carbon dioxide and acetate on lysines.

This process is involved in diabetes, Alzheimer's disease, arthritis, and other degenerative diseases, probably including osteoporosis. Mitochondrial damage tends to increase the production of lactic acid instead of carbon dioxide, and lactic acid can stimulate the inappropriate overgrowth of blood vessels, as occurs in the eyes in diabetes. During stress and aging, free fatty acids appear in the bloodstream in large quantities.

Besides their chemical effects, which lead indirectly to chronic disruption of signalling systems, the unsaturated fats have direct and immediate effects on regulatory processes, water uptake, intercellular communication, and excitation. Cell proteins have an affinity for fats, and their hydrophobic surfaces tend to adsorb them. Unsaturated fats have a greater affinity for water than saturated fats do, and the location

of the unsaturated bonds along the fat's carbon chain will affect the ways proteins interact with water. The fact that animal cells synthesize only fatty acids with a chain of eight fully saturated carbon atoms in their tails undoubtedly has something to do with the toxic effects of other unsaturated fats on the respiratory apparatus.

The unsaturated fats that are so systematically disruptive to warm-blooded animals are characteristically produced in plants at relatively low temperatures. In organisms that live at low temperatures, they probably serve a function (among others) that is analogous to the function of estrogen in warm animals, namely, raising the "structural temperature" of water, modifying chemical activity by liberating water to some extent from the domination of the cellular proteins.

One of the old theories of aging was that something (they called it metaplasm) accumulated in cells as a result of metabolism, the way ashes accumulate in a stove. Lipofuscin, or age- pigment, is related to the oxidation of unsaturated fats, and has been proposed to be such a material, that progressively limits a cell's adaptive capacity because of its physical and chemical properties. Amyloid, a clear mass of protein deposited in and around cells, is another such age or stress-related material, that is currently being studied in Alzheimer's disease and other degenerative diseases. Glycation, the attachment of sugars to groups that otherwise could be occupied by carbon dioxide, seems to be a crucial factor in the formation of amyloid. (The term "amyloid," in fact means "starch-like.") Changes in the extracellular matrix, for example the cross-linking of collagen molecules, have been thought to cause some of the characteristic changes of aging, and again, glycation is the major mechanism in the formation of cross-links.

In Alzheimer's disease, the commonly recognized features are tangles, amyloid deposits, hypometabolism, and evidence of inflammatory processes. Cells related to inflammation can produce amyloid, as well as remove it. Glycation, the attachment of sugar molecules to proteins, can happen quickly, and can occur either with or without enzyme catalysis. The failure of glucose consumption and of carbon dioxide production in Alzheimer's disease predisposes to glycation.

Glycation imitates mutated forms of proteins, for example normal transthyretin behaves like the prion protein, forming amyloid. Transthyretin, the protein that carries thyroid hormone and vitamin A, is normally taken up along with cholesterol under the influence of

thyroid hormone. Abnormal cholesterol metabolism is one of the traits associated with Alzheimer's disease. In the absence of thyroid-supported respiration, carbon dioxide and other respiration-associated molecules (e.g., acetate) are replaced by lactate and unused sugar, causing abnormal modifications of proteins such as tau, which regulates microtubule assembly. Glycation of collagen in the extracellular matrix alters the properties of the matrix. The glycated matrix would become a preferred site for glycated prion-like proteins.

It is possible that the altered transthyretin makes vitamin A less available to cells. Vitamin A deficiency creates major disruption of the framework proteins. Fragments of starch molecules inhibit the enzymes that remove inappropriately bound sugar molecules from proteins, and the inability to metabolize sugar into carbon dioxide increases that binding. Starches and unsaturated fats cooperate in this process of inappropriate sugar binding, while thyroid hormone, and the carbon dioxide it produces, tend to prevent the binding.

Considering the universal importance of carbon dioxide to life, the ways it interacts with all of the important substances that make up organisms, that it is involved closely with ATP synthesis and other "energy-related" processes, that it participates intimately in the regulation of water and ions, that it is therapeutic in a range of conditions including angina pectoris, hypoxia, epilepsy, inflammation, shock, lipid peroxidation, pneumonia, and asthma, I think we can at least conclude that it is a largely overlooked mediator between chemical energy and life processes. In many cases, its movements and reactions constitute the actual motive force that so many fantasy theories have failed to explain. In other situations, it fills out the context for understanding the energy-mediating actions of ATP, calcium, and hormones.

In the special arrangement of matter that is the living state, in which the most common events involve processes that are so close to equilibrium that some of them can be thought of as oscillations in an elastic system, carbon dioxide participates in both enzymic and nonenzymic reactions that produce, conserve, transfer, and transform energy. In its quickly reversible binding to protein amino groups, for example, it alters the protein's electrical charge, its folding, and its manner of associating with water and other substances. Its availablility to occupy these groups protects them from attack by substances that would degrade the organism's energy and structure. If the protein, water, ionic system

is thought of as energized matter, like a wound-up watch spring, it is the formation of carbon dioxide which has energized it and stabilized it.

Energy and Structure in Biological Water

A New Approach to Aging, Metabolic Inefficiency and Cancer

Energy and Character, Volume 4, Number 3, 1973

Biochemistry and even biophysics tend to be ruled by an emphasis on structure, at the expense of energy or function. The popular unit of biological energy is the chemical bond energy of ATP, a concept which has been notoriously unproductive in attempts to understand biological energy transformations such as nerve and muscle function, amoeboid movement, cell division, etc. That molecular concept of energy, despite its popularity, is derived from chemical equilibrium studies, and is not really applicable to the non-equilibrium, "steady state" conditions of life.[1] The study of biological energy transmission, transduction, and integration have been shunned, in favour of static models—for example, a famous researcher in "cell motility" has spent thirteen years manipulating wooden blocks representing molecular structures. Nevertheless, there is now enough information on the physics of macromolecules, water, and electrons and their interactions to support some very detailed interpretations of biological functions, including such well known, but hard to understand, interactions as memory and molecules, hormones and desires, emotions and cancer, loss of curiosity and aging, etc.

Prolonged discharge or activation of a cell tends to consume the molecular reservoir of energy, to "lower the energy charge" of the cell. Various physical measurements suggest that this is accompanied by an actual "melting" of the protoplasm. "Melting" does not necessarily mean going from hard to soft, and doesn't require changes in temperature. The general meaning of the concept as it is used here is "a phase transition from relative order to relative disorder." Glass, though very hard, is considered not to be a true solid because of its molecules' random arrangement. Likewise, fluid water can have different degrees of internal order, or structure, depending on its temperature,[2] its "history"[3] (its state during the last several hours) and its distance from a surface.[2] The proton, or hydrogen, component of the water molecule aligns itself with an electromagnetic beam, and so the freedom of water molecules can be measured by determining the nature of its absorption at certain frequencies. Such measurements have revealed that the water in tissue

is more highly ordered than ordinary water, and that cancer[4] and fetal[5] tissue and other new growth contain more water but their water is more like ordinary water, or more "melted."

In the presence of oil, or any unwettable surface, water becomes immobilized and ordered; conversely, ordered water will admit oily molecules more readily. Hydrophilic chemicals, such as sugar, will dissolve more easily in ordinary or relatively "melted" water: cancer cells are known to take up more glucose than normal cells do; insulin probably has a similar effect (a melting of the general protoplasm, follows insulin treatment).

Otto Warburg[6] related what he called "structure" to the ability of cells to use oxygen and to the ability of tissue to differentiate. He believed that evolution to the multicell stage depended on the existence of atmospheric oxygen. For several decades he gathered evidence to support his theory that cancer resulted from damaged respiration. However, his concept of "structure" was limited to such cellular components as the mitochondrion.[7] His general theory has withstood every challenge over the last thirty years.

If the cancer process represents a self-stabilizing reversal of evolution to the single cell stage, it can also be considered as a reversal of ontogenesis to a very early stage of embryonic development. Several theories have been based on the similarities of cancer to the early embryo (metastasis, non-allergenic proteins).

At the blastula stage of development, the embryo suddenly begins to consume large amounts of oxygen. As oxygen consumption increases, the water content decreases,[8] so that what remains is increasingly "surface" dominated, that is, on the average it is closer to macromolecules. Therefore, it must be more highly structured. The excited electronic state of oxygen is stabilized by cell water, just as the excited state of many fluorescent molecules is stabilized by ice, but not by ordinary water. This stabilization of the excited state could facilitate oxidation. Stabilization tends to be mutual; if this is the case, then oxidation might support structure in the water.

The fact that structured water promotes protonic conduction as well as prolonged electronic excitation should extend the range of molecular interaction, possibly even to the extent of intercellular adhesion. This would provide an explanation for cancer cells' loss of adhesiveness which results in secondary cancer growths. Resonant stabilization of one cell by

another would similarly account for the "contact inhibition" of normal cells. In the "melted" state cells would be limited to the less efficient anaerobic metabolism, because of the altered solubility and stabilization of oxygen, but they would maintain the primitive function of growth. If hydrostatic pressure can be considered to interfere with cell water structure,† this view would predict the observation of Chumak[9] that high pressure shifts the metabolism of bacteria from oxidation to fermentation. However, very high pressures can also interrupt cell division; growth under such conditions can lead to very long cells.

Free electrons in water will stabilize themselves by forming cages of water molecules around themselves, because of the electrically polar nature of water molecules. They are known to be much more stable in ice than in liquid water, and might be similarly stable in cell water. These electrons in solution have a deep blue colour, and are probably responsible for the blue colour of water and ice, which becomes much more intense at high elevations where free electrons are more abundant. If the structure of water in healthy cells is such that it would stabilize solvated electrons, then an abundance of free electrons should tend to stabilize the normal structure of cell water.

These concepts provide a new perspective in which to consider brain function and other processes in which pattern is essential, including tissue development. Instead of a computer with neuronal "wires," the brain can be viewed as a living jelly, in which nerves might have only a nutritive and transport function, with information storage and retrieval and consciousness in general being a hologram-like function of patterned flows of electrons through a very finely structured protein-polysaccharide-lipid-water gel. In this model, an act of consciousness (a structured flow) is simultaneously retrieval and storage, since structure will be modified or intensified according to the form of the flow, yet the flow will also be governed by the structure. Growth of generalized insight is synergic with intensity of experience, according to this model. This simple conception, derived from physical and metabolic studies,[10] is able to explain complex integration and message transduction, but its most outstanding advantage over the computer model is its ability to explain the experience of time in terms of an energy gradient which

† *cf.* The effects of stasis on the body fluids in Reich's account of cancer.

is known to exist (measured as a positive charge of the anterodorsal surface) and to correlate with changes in subjective states.

Palladin,[11] who demonstrated that innervation governs enzyme activity, has more recently found that efficient use of oxygen for energy production by brain tissue increases with evolutionary level (in reptiles, birds, and mammals) and with the degree of alertness. Level of brain activity and local innervation have been found to be involved in tumor growth,[12] and in the ability of tissue to form a reactive inflammation. These themes of enzyme activity changes and efficiency of oxidative metabolism, which are so important to the problems of evolution, consciousness, growth, and cancer, can be seen in the perspective of water structure with very surprising results.

Certain enzymes are inactivated by cold, and reactivated by moderate warmth; other enzymes are activated by the presence of molecules known to structure water, and inactivated by structure breakers, such as the fluoride ion. The enzymes which are activated by the relative disorder of warm water happen to be the enzymes which control a pathway of energy metabolism which becomes active in the growth state. Estrogen, chemical carcinogens, radiation, and lack of oxygen are known to activate this pathway. Normally, the energy produced by these reactions provides for regeneration following injury. Nerves, hormones, physical structures, and oxygen normally intervene and restore the high energy metabolic system necessary for differentiated functioning. If any of these factors is inadequate, the new tissue can stabilize into cancer, with its own "toxohormone," its own peculiar physical environment of abnormal connective tissue, and its own system for "wasting" oxygen,[13] all of which maintain the "melted" state of protoplasm with its primitive metabolic pathways. The other enzymes that are activated by structure, tend to be implicated in the high energy processes, and may suggest new approaches to the treatment of cancer.

Burr,[14] and more recently Becker,[15] have found that organ development is governed by an electric charge gradient in the organism. This gradient declines with age. Individual cells drift toward the inefficient oxygen wasting mode of metabolism with increasing age. Tissue electrical resistance increases with age. Accumulation of material between cells and disorganization of cell water probably contribute to the poor conductivity. It is possible that the high concentration of free electrons at high elevations increases the life span by helping to maintain the

high efficiency cell structure. (Vitamin C, a source of fairly high energy electrons, is known to support normal fetal development, even in the presence of powerful drugs which act by blocking respiration.)

Time-spanning is essential to consciousness; insightful perception seems to depend on the ability to directly perceive patterns that extend through time. Time is needed for consciousness to complexify, to have insights. But eventually, this growth function of time is directly subverted by another function of time, which insulates, lowers energy, shortens the time span of perception, and causes tissue degeneration. Possibly the simple interactions of electrons and water, energy and structure, will suggest new approaches to the treatment of senescence and associated diseases.

Estrogen Stimulated Pathway Changes and Cold-Inactivated Enzymes

Physiological Chemistry and Physics, Volume 4, April, 1972

It is well established that water near surfaces, including macromolecules and biological material, is very different from bulk water,[1] although the degree of ordering and the distance to which an effect is exerted are still in dispute. Shereshefsky,[2] Bernal,[3] Derjaguin,[4] Drost-Hansen[1] and others[5] have argued for an effect of surfaces on water structure at distances up to hundreds of Angstroms, or even farther. NMR studies have shown that tissue water is more restricted than bulk water, and that the water in young[6] or actively dividing tissue such as cancer[7] (which contains a higher than normal percentage of water) is more "bulk-like" than the water of more mature and stable tissue.

Temperature anomalies of enzyme activity have been attributed to solvent effects as water undergoes minor phase changes.[1] Cold-inactivation and cold-activation of certain enzymes probably represent extreme cases of such "anomalous" behavior, and at least for enzymes with more than one subunit, can be accounted for by the fact that hydrophobic bonds tend to be weakened by decreasing temperature.[† 89, p. 7010]

In an earlier paper,[11] we suggested that estrogen may act through an effect on the energy charge and the water structure of uterine cells, and that this very general effect may explain why various non-specific insults (e.g., radiation,[12] possibly hypoxia,[13] and diverse substances such as carcinogens[14] and histamine[15, p. 265]) have an estrogenic effect. Even age may have an effect similar to estrogen.[16–18]

It has recently been brought to our attention (A. R. Larrabee, personal communication) that fatty acid synthetase is cold-inactivated, and also that its activity in rat liver drops very sharply as early as two hours after feeding is stopped. This inactivation by cold has been attributed to dissociation resulting from weakening of hydrophobic bonds at low temperature.[19] Since lipid is the first substance to increase greatly in concentration in the estrogen activated uterus (although other compo-

[†] "…remember that thermal energy [kT] tends to disorder structures and, conversely, a lowering in temperature will increase the ordering."[1, p. 186]

nents show very early incorporation of label following estrogen stimulation[20, p. 1]), this fact is extremely interesting in relation to our proposal that estrogen increases the "structural temperature" of cell water, and so would tend to activate the cold-inactivated enzymes.

The other cold-inactivated enzymes from various organisms and tissues include pyruvate kinase,[21] glutamate dehydrogenase, ATPase, arginosuccinase, glycogen phosphorylase, pyruvate carboxylase, glucose-6-phosphate dehydrogenase, 17β-hydroxysteroid dehydrogenase,[8] acetyl CoA carboxylase,[22, p. 304] and the "muscle" or electrophoretically slow moving isozyme of lactic dehydrogenase,[23,24] which would also be suitable for regulating pathway changes involved in cellular activation. For example, phosphorylase activity is promoted by estrogen treatment.[25] Glycogen breakdown can be rate-limiting for glycolysis.[26, p. 572]

Estrogen stimulation, hypoxia, and carcinogenesis involve an increased proportion of the "muscle" isozyme of lactic dehydrogenase, which represents a useful adaptation to a glycolytic production of pyruvate that is larger than can be oxidized by the mitochondria or otherwise disposed of, since this isozyme can continue to oxidize NADH and reduce pyruvate even in the presence of high concentrations of pyruvate.[27]

Entropic activation of pyruvate carboxylase could tend to increase fixation of carbon dioxide[28] and production of oxaloacetate, which by transamination would increase aspartate concentration. According to Jervell et al.[29] the labeled aspartate pool (from $H^{14}CO_3$) is increased by estrogen to a greater extent than that of glutamate, suggesting that it, and its α-keto acid, oxaloacetate, are near the point of CO_2 fixation.

Barker and Warren[30] showed that the glucose-6-phosphate oxidation pathway is immediately activated by estrogen, yet the specific activity of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase decreased for the first six hours. Activation of these enzymes and raising of the NADP/NADPH ratio by the estrogen activated transhydrogenase, or by lactic dehydrogenase,[31] and even CO_2 fixation could contribute to the acceleration of this process.

It has been found that estrogen binding capacity of the uterine "receptor" molecule is considerably reduced at low temperature, and that the binding capacity is restored by raising the temperature,[20, p. 1] and Talwar et al.[32] reported that the rate of binding of estrogen to a soluble uterine fraction increases with incubation time as well as with temperature, indicating a kind of cooperative interaction. It has been proposed that

this change of binding might represent a temperature dependent transfer to the nuclear receptor, but Talwar's use of a "purified" extract argues against this view. The data relating to temperature effects on binding are consistent with the idea of a phase shift promoted by estrogen. Ling[33] has reported that progesterone increases the potassium selectivity of myometrium. Cone and Tongier[34] and Orr et al.[35] have found that the Na^+/K^+ ratio can very rapidly affect mitosis and DNA synthesis. Mueller et al.[36] observed that incubation in Eagle's medium can mimic estrogen stimulation. Such considerations suggest that it might be worthwhile to study the receptor protein as a possible initiator of phase transition, as an alternative to the view that it primarily serves to transfer estrogen to the nucleus.

Engel[37] has reported that one of his estrogen activated transhydrogenases has an affinity and specificity for estrogen comparable to that of the "receptor" protein, although the 17β-estradiol dehydrogenase has a lower affinity. If an intracellular enzyme binds estrogen and has its function modified by it, it is a receptor, but there is no evidence that the well known "9 S" receptor has enzyme activity. One of the seemingly well established "coenzyme" functions of estrogen is in the estrogen activated NADH oxidase function of peroxidase.[38] Peroxidase is "induced" in the uterus by estrogen treatment.[39]

Temple et al.[40] found that the oxidase behaved "like an induced enzyme," except that "oxidase activity was stimulated by the administration of estradiol to oophorectomized rats in two hours, when net protein synthesis cannot be detected." "Receptor" protein is also "induced" by estrogen.[41,42] Whatever the relation of "receptor" to estrogen activated enzymes might be, the apparent oxygen wasting effect of the estrogen activated oxidase would help account for estrogen's ability to lower the Pasteur effect[43, p. 348] and to lower the pO_2 of the uterine lumen,[44] and this effect would be compatible with the above mentioned diversion of pyruvate to oxaloacetate (which would tend to inhibit succinic dehydrogenase) and with the shift[44] toward M isozymes of LDH, which appears to correspond to hypoxia and would also divert pyruvate from oxidation. A consequent reduction of the energy charge might cause the phase change, or damage to structure as suggested by Warburg.[45, p. 327] Racker[46] has recently proposed that increased temperature or altered pH may be involved in activation of the glycolytic pathway in cancer, and suggests increased hydrolysis of ATP as a possible cause. It was Racker

who first observed that mitochondrial ATPase is cold-inactivated, and he has also pointed out that damage to mitochondria can reveal very high levels of ATPase activity.

Other physiological processes that might be accounted for by an entropic modification of protein association and enzyme activity include:

(a) ammonia formation by stimulated nerve,[47] muscle,[48] and uterus,[†] since glutamate dehydrogenase is among the known cold-inactivated enzymes and these tissues[‡ 49,50] seem to undergo a water phase change when stimulated;

(b) estrogen stimulation of water uptake, by a thermo-molecular pressure effect,[51] because of increased metabolic rate[52] and possible change of heat conductivity,[1] or by a more direct effect on gel structure;

(c) estrogen's effect of increasing ATPase activity of the uterus,[53] which might relate to the increased myometrial reactivity in the estrogen dominated uterus;

(d) microtubule formation, since these seem to be cold sensitive;[54] also, H. Nemetschek-Gansler,[55, p. 353] in describing the ultrastructure of the myometrium under the influence of estrogen says that the appearance "suggests a high degree of depolymerization of the contractile proteins," and that progesterone produces something like syneresis, implying altered protein-water interaction;

(e) vernalization.[1] This is a process involving an actual and large temperature difference rather than merely a structural difference. Cold-activation of enzymes would be the expected mechanism.

Abdulla and McFarlane[56] suggest that since a pyrophosphatase is activated or "induced" on the surface of platelets by collagen, and inhibited by NaF, this enzyme may belong to a class of enzymes activated by solvent structure. It has been proposed that association in some cases blocks active sites. In such cases increased solvent structure would increase activity or lower substrate specificity, if it weakened hydrophobic bonds.

[†] Inferred from observations in this laboratory.
[‡] NMR studies currently being done in this laboratory.

(Xanthine oxidate is well known as a cold-activated enzyme,[57] possibly involving such a mechanism.) Since pyrophosphatases are involved in establishing equilibria favorable to synthesis of protein (amino acid activation), RNA, and DNA, and oxidation of fatty acids, the concept of activation by solvent structure would imply that these processes belong to a later period in cell activation, in which a certain degree of order has been restored. The known schedule of syntheses following estrogen stimulation is consistent with this view. Either androgen or progesterone, which can increase metabolic "efficiency,"[58] would probably be involved at this stage. Progesterone's thermogenic[28] and anesthetic[59] effects seem significant in this context. A theory recently proposed[60–62] for control of enzyme levels could account for apparent induction or repression by cytoplasmic stabilization of some proteins, and by destabilization of others.

This entropic and energetic interpretation presents dedifferentiation as a simple, stable, and general change of state. Differentiation remains as a highly individualized process, depending on a precise history and environment of each cell. However, the simplicity of this view of dedifferentiation suggests a relatively small number of points at which effective intervention might be made in altering the course of carcinogenesis. It also suggests possible new approaches to fertility, sterility, and aging.

Estrogen in 1990

Townsend Letter for Doctors, April 1991

The Magic of Estrogen Therapy

A stage magician can produce surprising illusions by directing the audience's attention to where something is not happening, or to a distracting gesture. The billion-dollar estrogen industry has learned the trick of directing the public's attention to where some plausible benefit might be expected, and of politely ignoring the areas where death and destruction are in fact being produced.

Interestingly, another billion-dollar industry—the edible oil industry—is using the same prestidigitation to profitably misinform the public. Decades ago, unsaturated oils were found to lower cholesterol. However, studies showed that adding the polyunsaturated oils to the diet didn't prevent death from heart disease, but that it did increase cancer deaths. There were also warnings that the oils could cause problems with blood clotting. There was silence from the industry, the government, and the medical profession in response to the bad news.

When evidence of an association between blood lipids and heart disease was found, the blood tests, rather than actual health, became the focus of publicity. A high ratio of HDL (high density lipoprotein) to LDL (low density lipoprotein) came to be identified with "health," because of its association with lower risk of heart disease, although it was also an indicator of a risk of death from cancer. By ignoring everything but heart disease, it could be argued that "If high HDL equals health, and estrogen and PUFA (polyunsaturated fatty acids) cause HDL to increase, then these things promote health."

Concerning estrogen, similarly twisted reasoning led to its trial in the 1960s to prevent heart attacks in men, but the experiment was stopped when the rate of heart attacks increased sharply.

Focus on the positive. Ignore the HDL-cancer association. Ignore the association of estrogen with thrombosis, embolism, stroke, edema, obesity, depression, myocardial infarction, eclampsia, epilepsy, brain damage, and immunodeficiency. Ignore the implications of thyroid suppression.

In her comedy routine, Judy Tenuta describes a most implausible situation, and then belligerently pleads: "It could happen; it could happen." The ignorance or mendacity which allows experts to plead the importance of one possible benefit, in the face of clear evidence of a multitude of serious dangers, defies any sort of conventional scientific response.

The recent corruption scandal involving the FDA's generic drug division might come to mind when I suggest that Tenuta's satire illuminates the attitude of the FDA (and the medical industry), but I believe the indictments are part of the prestidigitation. Marvin Seife, who was head of the generic drug division, was indicted for perjury. The indicated intent of Congress had been to support generic drugs to break the monopoly of the biggest drug companies; but for the last six years there has been an intense campaign by the monopolies to keep generic drugs off the market, and Seife's indictment must be evaluated in this context.

Earlier, an FDA official who was too friendly toward DMSO and its developer, Dr. Jacob, was exposed for accepting a loan from the doctor. While keeping new entrepreneurs from intruding into the fabulously lucrative drug business, those little prosecutions allow the public to believe that the government is policing itself. (If your corporation could expect an additional $4,000,000,000 in profits in the next 10 years, but only if a few men would narrow the scope of their judgment, how do you suppose you could encourage those few men to go in the right direction?)

Just One Problem: Clots

Forty-five years ago the Shutes found that estrogen promotes the clotting of blood. At the same time, Knisely was studying the phenomenon of "blood sludging," which occurs under many types of stress. At that time it was recognized that there is an equilibrium between clot formation and clot removal (fibrinolysis).

Vitamin E and magnesium and some substances produced by the body shift the balance away from clots. Estrogen, calcium, altered water content and blood volume, and sluggish flow of blood encourage the formation of clots. Some contemporary articles acknowledge that estrogen can cause thrombophlebitis or thromboembolism and can exacerbate

gallbladder and liver disease and breast cancer, but these warnings are subordinated to praising the benefits of estrogen replacement therapy.[1]

Some quotations from the ERT article by Miller, et al.,[1] illustrate current medical attitudes.

"Although the reasons for its apparent protective effect on the heart are not fully understood, oral estrogen does decrease low-density lipoprotein cholesterol and increase high-density lipoprotein cholesterol."

"Although no prospective study has yet shown that estrogen protects against cardiovascular disease, other studies show that women who use estrogen or who have ever used estrogen have a reduced risk of heart disease. The only study that has not confirmed these results is the Framingham Heart Study, which contained smaller numbers of older women and classified chest pain—a notoriously poor identifier of heart disease in women—as a cardiovascular end point." (p. 47)

The prospective long-term Framingham study noted above used to be highly praised as a source of reliable information on heart disease. In contrast, some of the studies that are praised in prestigious journals are wildly unscientific. For example, the heart disease in Marin County women receiving estrogen has been compared with that of women in the East Bay not getting estrogen. Marin County is a rich residential area, which is swept by ocean breezes while across the bay there are more working class people (and working class men are known to have nearly 50 % more heart disease than white collar workers), and the wind from one direction blows smoke from a concentration of industries and refineries, from another direction it carries the pollution from San Francisco's traffic, and from another direction it brings the agricultural poisons of the Salinas area.

If enough women die from strokes, pulmonary embolisms, accidents, suicide, cancer, and loss of immunity caused by estrogen excess, it is possible that some competent study will eventually show that estrogen treatment reduces the mortality from heart attacks, but this is not likely.

It is the estrogen in oral contraceptives which correlates with their effects on the clotting system. In the last 20 years there has been general agreement that increased risk of cardiovascular disease, rather than cancer or immunodeficiency or depression, is the most important concern about the effects of oral contraceptives.[2–12]

There are many ways that estrogen can contribute to a hypercoagulable state (leading to cardiovascular disease). Some of these involve

altered liver function, including disturbed production or metabolism of 8 different coagulation controlling factors.[13,14] Since estrogen can stimulate endothelial proliferation (often cited as crucial in heart disease) and reduces the rate of venous flow,[15,16] it is necessary to consider the whole complex circulatory system, and not just the clotting factors.

The thyroid and other hormones such as insulin and adrenalin are influenced by estrogen, and must be taken into account. Although I'm not sure what clinical perceptions led the Shutes to study estrogen's affect on clotting, pregnancy and lactation are notoriously associated with hypercoagulability (eclampsia and thromboembolism, for example) produced by the body's high estrogen production at those times.[17–24] The very high doses of estrogen that were once used to suppress lactation were found to produce clotting problems.[25] Postmenopausal use of estrogen causes changes in coagulability.[13,14,26]

In the mid-1970's when I pointed out that menopause resembles Cushing's syndrome[27] I hadn't investigated that disease of cortisol-excess enough to know the full extent of the parallel: for example, hot flushes, night sweats, and insomnia, such common menopausal symptoms, are also common symptoms in Cushing's syndrome. Estrogen's tendency to increase cortisol production should be considered in connection with the brain-aging effects of both estrogen and cortisol.[28,29]

Both estrogen and cortisol weaken the structural components of tissue, and the bruising which is so commonly associated with the premenstrual syndrome seems to involve the unopposed action of both of these hormones. The women who often have bruised thighs in their twenties are later susceptible to hemorrhages into the white part of the eye, and still later to bleeding into the brain, presumably because there is a hierarchy of protection against the tissue-weakening effects of those hormones, with the brain being the last to lose its resistance.

For example, the brain content of progesterone, pregnenolone and DHEA is normally 20 or 30 times higher than the serum concentration, and these hormones are protective against both estrogen and cortisone. As far as I know, it is possible to have fragile blood vessels at the same time as an excessive tendency to clot, though when the vessels break, the extent of the bleeding will be smaller in the hypercoagulable state. The observation that low cholesterol is associated with increased risk of hemorrhagic stroke[30] suggests that the age-related decline in progesterone,

pregnenolone, and DHEA occurs earlier when there is a low level of the precursor substance, cholesterol.

Clotting too easily is just one of the problems that can be caused by an excess of estrogen, and I don't mean to give it too much emphasis, since I consider its toxic effects on the brain, and its acceleration of brain aging to be its worst effects—though its cancer inducing effects on the uterus, the breast, the lung, the bowel and liver, and brain, are certainly serious. But in 1990, estrogen's cardiovascular toxicity is probably the aspect that people need to be reminded of.

Failures of Immunity

Townsend Letter for Doctors, December, 1992

FROM ancient times until the 1940s, young adulthood was the healthiest phase of life, with an insignificant rate of death from disease. Septicemia, bacterial infection in the blood, had been associated with the natural immune deficiency of old age. By the 1960s septicemia was killing many young adults, in spite of the susceptibility of the germs to antibiotics.[1,2] The use of antibiotics did save enough immune deficient people from septicemia to allow an increasing incidence of other diseases, including *Pneumocystis carinii* pneumonia, to become apparent. Acquired immune deficiency (AIDS) was a recognized syndrome for many years, and it was known to be increasing long before the 1980s.[3]

P. H. Duesberg had made the point that most of the present AIDS epidemic can be explained by the various known causes other than the HIV virus. I think he is mostly right, but I don't exclude the possibility that the virus in itself could be a significant cause of the disease. My judgement would be that the virus is a "co-factor" in the disease, and by this I mean that we have been exposed to an increasing burden of immunosuppressive factors, which are causing an exponentially rising curve of immunodeficiency diseases, and that, arriving at a certain point on that curve, the HIV virus would help to push the rate of increase upward.

Besides the generally increasing industrialization and pollution, in the 1950s there were sudden increases in our exposure to several powerfully immunosuppressive factors. Radioactive fallout (especially strontium 90, which concentrated its damage near the bone marrow), medical X-rays, dioxins and other chlorinated carbon compounds, insecticides and herbicides, the increased promotion of the use of liquid vegetable oils as food, and the use of lead as a gasoline additive, had all become important immunosuppressive factors by 1960. The relative importance of these varied with the person's age, vocation, customary diet, social class, etc. For example, rich people were more likely to have prenatal X-rays, and poor people were more likely to have lindane applied to their skin to kill lice.

A low level of the hormone DHEA is associated with premature death from various causes, including cancer, heart disease, and AIDS.

DHEA is one of the youth-associated, energy-promoting, anesthetic steroids which I have described as essential to our natural resistance. (For example, in *Natural Immunity and Viral Infections*, I said "Pregnenolone, progesterone, DHEA, and pregnanediol are all good candidates as antiviral drugs, but etiocholanolone—which also produces fever—is the most interesting of the group.") In general, the things that lower vitality and immunity interfere with our ability to produce the protective steroids.

Those hormones are made from cholesterol, and both low and high concentrations of blood cholesterol are associated with immune defects. Most of the people I have talked to who have multiple serious allergies have very low cholesterol levels, and hypothyroid people who are very susceptible to infections usually have high cholesterol, and in both situations there isn't adequate production of hormones from cholesterol.

Often, the idea of "auto-immune disease" serves as an excuse for the use of immunosuppressive treatments, such as glucocorticoids or methotrexate, so I usually avoid the word and the concept. Antibodies against specific tissues are probably part of a normal process to take care of damaged cells. For example, simply twisting a piece of cartilage makes it antigenic. After talking to many people who had anti-thyroid antibodies which disappeared soon after their thyroids became normal from physiological therapies, I decided that "auto-immune" antibodies were useful to indicate which organ was under stress, but shouldn't be taken as a sign of an "immunological disease." Still, the immune system, like any system, can become ineffective or sick, and it is possible that a sick immune system could make some problems worse. (I have previously used the analogy of an "allergy" to discuss this view of AIDS.)

Morphine has been known to be immunosuppressive for several decades, though this fact has been ignored in prescribing it for cancer patients. (Intravenous ethanol has a protective effect on the immune system, and is as effective as morphine in controlling the pain of cancer.) Morphine's directly suppressive effect on immunity isn't understood, but there is some suspicion that it relates to the stress-induced immunosuppression (loss of natural killer cell function, for example), acting in place of stress-induced endorphins. White blood cells, like nerve cells, have surface "receptors" for morphine, which normally would be acted on by the endorphins. As an abnormal material bound to the cell surface, it probably constitutes a "hapten," something sensed by other white

blood cells as foreign. It would be healthy to eliminate such abnormally modified cells, and even possibly to eliminate the cells that contain the natural endorphin molecule. But in a weakened organism, the formation of new cells might lag behind the elimination of modified cells.

Deusberg has said that it seems illogical that a person should get sick, just as he is beginning to produce large numbers of antibodies to the HIV virus, but it wouldn't be illogical if the antibodies were eliminating cells faster than they could be replaced. His point, that only one cell in 100 carrying the virus isn't enough to cause failure of the immune system, is true, other things being normal. But an allergy can be triggered by very small quantities of allergen. In a failing immune system, a few molecules of morphine or a few viral antigens could be enough to trigger a kind of autoimmune/allergic response, which could cause a massive suppression or disorganization of immune function.

But even if such a thing is involved in AIDS—even if the HIV virus is a true cause of AIDS—Duesberg is right in emphasizing that we have to think of immune deficiency in a broader context, of eliminating all the immunosuppressive factors, and understanding the real nature of the immune system.

If antibodies turn out to be part of the problem, we shouldn't think of searching for additional immunosuppressive drugs, because we already know of situations in which antibody production increases while immunity is being impaired, as if in compensation for a weakness in cell-mediated immunity. Increasing the production of the cells that are deficient and improving their functioning, should be the focus of attention. The increased incidence of septicemia among young adults suggests that phagocytosis was deficient. Since Metchnikoff's time there hasn't been much interest in the phagocytes, but I think that is beginning to change.

Folic acid is so important for proliferation and differentiation that I think it's worthwhile to take about 5 mg daily for a week or two.

Vitamin A is important for resistance, but carotene can interfere with retinol.

Carotenemia suggests a lack of vitamin B_{12} or thyroid, and interferes with thyroid and steroid production.

Another thought: if you ate vegetables, whole grains and legumes in the 1960s, your bones are rich in strontium 90. Vigorous osteoclasts are working to get rid of it, by phagocytosis. Warm bones are young bones.

Gas Industry's "Shortage"

Science News, Volume 102, Number 12, September, 1972

PEOPLE who express confusion about the gas industry's story of short supplies and their search for new ways to increase consumption of gas, should read Robert Sherrill's "Energy Crisis! The Industry's Fright Campaign," in the June 26 *Nation*. He points out that in 1968 the U.S. Supreme Court rejected higher profits on gas because "each year new reserves exceeded production." Then "beginning in 1968, and for the first time in history, the industry claimed that it found less gas than it sold. It has been claiming the same thing for every year since. The basis for these claims is in industry's file cabinets, secret, not available to Congress or to the public."

An interesting contrast to this situation is that in the U.S.S.R., where energy is publicly owned, there is serious scientific discussion of the possibility that natural gas might be truly inexhaustible, as a result of continuous replacement in a natural energy cycle.

There is a similar contrast in our attitudes toward the fixation of atmospheric nitrogen by higher animals: The Russians have studied it for many years, while all but a few American scientists ridiculed the notion, preferring to talk about the "world protein crisis" and population control.

Hormone Balancing: Natural Treatment and Cure for Arthritis

The Journal of the Rheumatoid Disease Foundation, Volume 1, Number 1, 1986

A very healthy 71-year-old man was under his house repairing the foundation, when a support slipped and let the house fall far enough to break some facial bones. During his recovery, he developed inflammatory arthritis in his hands. It is fairly common for arthritis to appear shortly after an accident, a shock, or surgery, and Hans Selye's famous work with rats shows that when stress exhausts the adrenal glands (so they are unable to produce normal amounts of cortisone and related steroid hormones), osteoarthritis and other "degenerative" diseases are likely to develop. But when this man went to his doctor to "get something for his arthritis," he was annoyed that the doctor insisted on giving him a complete physical exam, and wouldn't give him a shot of cortisone. The laboratory examination showed low thyroid function, and the doctor prescribed a supplement of thyroid extract, explaining that arthritis is one of the many symptoms of hypothyroidism. The patient agreed to take the thyroid, but for several days he grumbled about the doctor "fixing something that wasn't wrong" with him, and ignoring his arthritis.

But in less than two weeks, the arthritis had entirely disappeared. He lived to be 88, but without a recurrence of arthritis.

Selye's work with the diseases of stress, and the anti-stress hormones of the adrenal cortex, helped many scientists to think more clearly about the interaction of the organism with its environment, but it has led others to focus too narrowly on hormones of the adrenal cortex (such as cortisol and cortisone), and to forget the older knowledge about natural resistance. There are probably only a few physicians now practicing who would remember to check for hypothyroidism in an arthritis patient, or in other stress-related conditions. Hypothyroidism is a common cause of adrenal insufficiency, but it also has some direct effects on the joint tissues. In chronic hypothyroidism (myxedema and cretinism), knees and elbows are often bent abnormally.

By the 1930s, it was well established that the resistance of the organism depended on the energy produced by respiration under the influence of the thyroid gland, as well as on the adrenal hormones, and that the

hormones or pregnancy (especially progesterone) could substitute for the adrenal hormones. In a sense, the thyroid hormone is the basic anti-stress hormone, since it is required for the production of the adrenal and pregnancy hormones. A contemporary researcher, F. Z. Meerson,[1] is putting together a picture of the biological processes involved in adapting to stress, including energy production, nutrition, hormones, and changes in cell structure.

While one of Selye's earliest observations related gastro-intes tinal bleeding to stress, Meerson's work has revealed in a detailed way how the usually beneficial hormone of adaptation, cortisone, can cause so many other harmful effects when its action is too prolonged or too intense. Some of the harmful effects of the cortisone class of drugs (other than gastro-intestinal bleeding) are: Hypertension, Osteoporosis, delayed healing, atrophy of the skin, convulsions, cataracts, glaucoma, protruding eyes, psychic derangements, menstrual irregularities, and loss of immunity allowing infections or cancer to spread.

While normal thyroid function is required for the secretion of the adrenal hormones, the basic signal which causes cortisone to be formed is a drop in the blood glucose level. The increased energy requirement of any stress tends to cause the blood sugar to fall slightly, but hypothyroidism itself tends to depress blood sugar. The person with low thyroid function is more likely than a normal person to require cortisone to cope with a certain amount of stress. However, if large amounts of cortisone are produced for a long time, the toxic effects of the hormone begin to appear. According to Meerson, heart attacks are provoked and aggravated by cortisone produced during stress. (Meerson and his colleagues have demonstrated that the progress of a heart attack can be halted by a treatment including natural substances such as vitamin E and magnesium.)

While hypothyroidism makes the body require more cortisone to sustain blood sugar and energy production, it also limits the ability to produce cortisone, so in some cases stress produces symptoms resulting from a deficiency of cortisone, including various forms of arthritis and more generalized types of chronic inflammation. Since cortisol is formed as one of the last steps in a series of reactions, glandular exhaustion means that a whole group of other steroids is depleted, before cortisol or cortisone. I believe that the safest way to handle a steroid deficiency is to supplement the precursors of the raw materials, so that a normal balance

of the various substances is preserved. Often, a small physiological dose of natural hydrocortisone can help the patient meet the stress, without causing harmful side effects.

While treating the symptoms with cortisone for a short time, it is important to try to learn the basic cause of the problem, by checking for hypothyroidism, vitamin A deficiency, protein deficiency, a lack of sunlight, etc. (I suspect that ultraviolet light on the skin directly increases the skin's production of steroids, without depending on other organs.) Using cortisone physiologically, rather than pharmacologically, it is not likely to cause the serious problems mentioned above.

Stress-induced cortisone deficiency is thought to be a factor in a great variety of unpleasant conditions, from allergies to ulcerative colitis, and in some forms of arthritis. The stress which can cause a cortisone deficiency is even more likely to disturb formation of progesterone and thyroid hormone, so the fact that cortisone can relieve symptoms does not mean that it has corrected the problem.

Besides the thyroid, the other class of adaptive hormones which are often out of balance in the diseases of stress, is the group of hormones produced mainly by the gonads: the "reproductive hormones." During pregnancy, these hormones serve to protect the developing baby from the stresses suffered by the mother, but the same hormones function as a part of the protective anti-stress system in the non-pregnant individual, though as a lower level.

Some forms of arthritis are known to improve or even to disappear during pregnancy. As mentioned above, the hormones of pregnancy can make up for a lack of adrenal cortex hormones. During a healthy pregnancy, many hormones are present in increased amounts, including the thyroid hormones. Progesterone, which is the most abundant hormone of pregnancy, has both anti-inflammatory and anesthetic actions, which would be of obvious benefit in arthritis.

There are other naturally anesthetic hormones which are increased during pregnancy, including DHEA, which is being studied for its anti-aging, anti-cancer, and anti-obesity effects. (One of the reasons that is frequently given for the fact that this hormone hasn't been studied more widely is that, as a natural substance, it has not been monopolized by a drug patent, and so no drug company has been willing to invest money in studying its medical uses.) These hormones also have the ability to

control cell division, which would be important in forms of arthritis that involve invasive tissue growth.

While these substances, so abundant in pregnancy, have the ability to substitute for cortisone, they can also be used by the adrenal glands to produce cortisol and related hormones. But probably the most surprising property of these natural steroids is that they protect against the toxic side-effects of excessive adrenal hormones. And they seem to have no side-effects of their own; after fifty years of medical use, no toxic side effects have been found for progesterone or pregnenolone. Pregnenolone is the material the body uses to form either progesterone or DHEA. Others, including DHEA, haven't been studied for so long, but the high levels which are normally present in healthy people would suggest that replacement doses, to restore those normal levels, would not be likely to produce toxic side effects. And, considering the terrible side effects of the drugs that are now widely used, these drugs would be justifiable simply to prevent some of the toxic effects of conventional treatment. It takes a new way of thinking to understand that these protective substances protect against an excess of the adrenal steroids, as well as making up for a deficiency. Several of these natural hormones also have a protective action against various poisons—Selye called this their "catatoxic" effect. (If a toxin, for example a bacterial product, is involved in a sickness, such as arthritis or colitis, these catatoxic steroids might be helping by blocking the toxin and strengthening the patient.)

Besides many people whose arthritis improved with only thyroid supplementation, I have seen people use one or more of these other natural hormones for various types of arthritis, usually with a topical application, and I know of several other people who used progesterone topically for inflamed tendons or other inflammations. Only one of these, a woman with rheumatoid arthritis in many joints, had no significant improvement. An hour after she had applied it to her hands and feet, she enthusiastically reported that her ankle had stopped hurting. But after this, she said she had no noticeable improvement.

The first time I saw arthritis disappear after treatment with progesterone was accidental. A woman who began using progesterone for her epilepsy decided to dip her arthritic fingers in the oily solution, and a few days later proudly demonstrated that she could bend them without pain.

About a year later, a friend in Mexico City complained about a knee that had been increasingly stiff and painful for about a year. 20 min after applying progesterone the pain was gone, and when I asked him about it a few years later, he said it never hurt again. Knowing that those "raw material" steroids, pregnenolone, progesterone, and DHEA, could be converted into anything the body needs, such as cortisone and sex hormones, but that they protect against the toxic effects of other hormones, many other people (including physicians and researchers) were interested in trying them on their own joint problems.

Some typical cases are described below:

1. A 72-year-old woman. She was considered to have mild rheumatoid arthritis which was degenerating into porosis, with her fingers being the most seriously affected joints. A 3 % solution of DHEA in olive oil was applied to one index finger, and a 10 % solution of progesterone in mixed tocopherols was applied to the other index finger. All of her fingers had been rigid for over a year, with the result that she was extremely disabled. 40 min after the DHEA solution had been applied, the finger treated with that solution could be bent enough to touch the base of her thumb, without significant pain, but none of her other fingers showed any improvement. Several days later, the DHEA solution was applied to all of her fingers, with similarly good results. After about 6 months, stiffness and pain returned in spite of her use of DHEA. Although thyroid was suggested, she had been taught to be afraid of that hormone, as have millions of other women.

2. A 60-year-old woman with a long history of rheumatoid arthritis had serious degeneration of many joints. She had undergone surgery several times, for implantation of two artificial joints and for repair of joint cartilage. She walked a little as possible and experienced pain, inflammation and fatigue with excessive walking. She applied a solution containing 7 % DHEA and 3 % progesterone in a solvent consisting of olive oil and tocopherol. She applied the solution several times one afternoon and the next morning to all affected joints, including hands, wrists, elbows, knees, and ankles. She experienced what she said was "complete relief," and spent the next two days walking around the town sightseeing, without any of the after-effects she had previously experienced from walking.

3. A 62-year-old man. His knees had been stiff, painful, and inflamed for over two years, following an accidental fall onto his knees.

Arthroscopic examination revealed damaged cartilage in his right knee, and surgery was recommended to restore function. The patient refused surgery, even though he walked with difficulty and had to use his left leg (which was also affected) to lift himself slowly up steps. He said he had not slept well since he had developed the arthritis, because the pain woke him repeatedly during the night, and only the use of an analgesic would allow him to go back to sleep. He coated his knees and the skin around them, about four inches above and below, with a total of nearly an ounce of a solution similar to that used in case number two. Within 30 min, he appeared to able to walk more normally, and about 45 min after applying the solution, he remarked that he believed he was able to walk more easily.

He repeated the application that night before going to sleep. Around 10 o'clock the next morning, he returned and laughingly demonstrated his knees by running up the stairs, and said that he had been able to sleep through the night for the first time in years, and had not taken his usual analgesic. Topical treatment was discontinued after a few days, and he remained free of symptoms while taking 60 mg of pregnenolone orally, daily.

4. A 61-year-old woman. Painful and stiff joints in her hands had interfered with her work as a musician, and had made it impossible to sleep through the night, since the pain woke her two or three times during the night. A solution similar to that used in cases three and four was applied to the painful joints early in the evening, and a few hours later she was able to go to sleep without taking aspirin and slept through the night. She occasionally uses the same solution preventatively, and has not had a recurrence of the joint pain or stiffness.

We often hear that "there is no cure for arthritis, because the causes are not known." If the cause is an imbalance in the normal hormones of adaptation and resistance, then eliminating the cause by restoring this balance will produce a true cure.

Informed patients who suspect that their health problems are related to stress should encourage their physicians to investigate the use of thyroid hormone, progesterone, pregnenolone, DHEA, and the anti-stress nutrients, especially magnesium and vitamins A and E.

Immunity, Hormones and Yeast Infections

Townsend Letter for Doctors, October, 1985

In understanding candidiasis, two things, related to each other, are of special importance: the involvement of the endocrine system, and the suppression of natural immunity. Similar endocrine and immune problems can occur in other situations: cancer, aging, viral infections, and chemical poisoning. Damaged cellular respiration appears to be the common mechanism. A skin test, using Candida antigen, based on the universal exposure and acquired immune reactivity to it, shows a similar lack of response in both systemic candidiasis patients and in cancer patients. In a study of cancer patients, nutritional supplementation increased skin reactivity and survival. According to R. A. Cox, energy of the cell-mediated immunity and a T-cell deficiency are found in chronic mucocutaneous candidiasis. In 1860, Trousseau said that candidiasis is "the local expression of a very bad state of the whole system." Similar observations have been made regarding cancer and tuberculosis.

Thyroid, progesterone and pregnenolone help to normalize blood sugar by improving respiration, and should be the basic treatment for allergies.

Another surprising similarity between candidiasis and cancer is that the antibody reaction might be harmful, rather than helpful. According to Diamond, "high levels of specific antifungal antibodies may sometimes block or inhibit the development of cell-mediated immunity to mycoses."

Simplified ideas of the immune system were fostered by the success of vaccination against certain diseases, and by the preference of most researchers for clearly defined single-level mechanisms. Influences from the environment, nutrition, hormones, and biological rhythms make the problem more complex, but few people have recognized the importance of nonspecific immunity and the organism's general resistance. Early in this century, light therapy was recognized to be effective for tuberculosis. Coley's toxins were another early and successful attempt to stimulate the immune system. W. F. Koch, working in Gomberg's lab with free radicals, postulated that free radical oxidation was central to natural resistance to infection and cancer. Similar ideas were developed by Albert Szent-Györgyi, and many others contributed supporting evidence

for the importance of respiration in resistance to disease—Otto Warburg, Max Gerson, and Broda Barnes, for example.

The two hormones, estrogen and cortisone, are associated with stress, with respiratory changes and with changes in the immune system.

A recent review article by C. J. Grossman[1] outlines the effects of estrogen on the immune system. Estrogen causes atrophy of the thymus, and depresses the circulating levels of thymosin alpha one: when estrogen is given to castrated rats, their serum has "a marked inhibitory effect on T-cell function," and "estrogen and androgen act mainly to suppress the cell-mediated immune system." Estrogen increases antibody production, which is not necessarily helpful in conditions such as candidiasis and cancer. Estrogen retards skin graft rejection, and this probably indicates how parasites will be handled.

An especially important effect of estrogen is its reduction of the amount of IgA antibody secreted at membranes—this is very likely to be the reason for the high incidence of vaginal yeast infections premenstrually and during pregnancy. Thyroid and progesterone both increase the secretion of IgA, and these hormones are frequently deficient premenstrually and in pregnancy.

Allergy and epilepsy consist of hyperactivity of, respectively, immune cells and nerve cells. Low cellular energy, caused by hypoglycemia or hypoxia, causes hyperactivity of any cell type; the easiest way to observe this phenomenon is in the delayed relaxation of a hypothyroid person's Achilles reflex, or a delayed repolarization wave in the electrocardiogram. Estrogen interferes with cellular energy in many ways, including a contribution to hypoxia by impairing oxygen absorption. Thyroid, progesterone, and pregnenolone help to normalize blood sugar by improving respiration, and should be the basic treatment for allergies.

Some fungi have been found to respond to the human sex steroids, estrogen and testosterone, and there is evidence for a corticosteroid receptor in Candida[2] suggesting that the yeast produces and responds to a hormone resembling cortisone. Estradiol, the most powerful human estrogen, has been extracted from a yeast.[3]

For many years, male beer drinkers have been known to develop breasts. Since liver damage causes abnormal amounts of estrogen to be produced and retained, the alcohol was blamed, but in the last year, enough estrogen was found in beer and wine to account for the condition, independently of any alcohol damage to the liver. Bread was also found to

contain significant amounts of estrogen, from the yeast. (The increased rate of cancer which has been observed in beer drinkers might have something to do with estrogen. It would be interesting to compare the cancer incidence among bread eaters with the incidence in people who eat tortillas, pasta, or potatoes.)

Since early in this century, brewers' yeast was used for treating diabetes. The pancreas has an estrogen receptor, and estrogen promotes insulin secretion. Since reading of yeasts' responsiveness to sex hormones, about 15 years ago, I have encouraged people to use liver when they need a vitamin-mineral supplement, and to restrict the use of brewers' yeast mainly to the treatment of diabetes.

Besides people who are debilitated from starvation, drug treatment, or old age, the main groups who have a high incidence of Candida infection are diabetics, pregnant women, and premenstrual women. Rosalinde Hurley lists susceptible conditions, including infancy, severe infections, leukemia and other defects in cell-mediated immunity, and endocrine disease; she also mentions that the unhealthy skin near ulcers is often colonized by Candida.

A high glucose concentration in body fluids would be an obvious factor in diabetics, and in some pregnant women, but blood sugar tends to be low premenstrually. Many diabetics have high levels of cortisone, and some women do in pregnancy or premenstrually, but the consistent feature of pregnancy and the premenstrual part of the cycle is an increased production of the sex steroids.

Since progesterone used to be called the "luteal hormone," many doctors have wrongly associated it with many premenstrual events, including water retention. Most medical textbooks make the same mistake. The corpus luteum secretes both estrogen and progesterone, and when the person is under stress, progesterone production fails, while estrogen secretion continues. Progesterone deficiency and estrogen excess very often occur in the "luteal phase," premenstrually, and in pregnancy, and at menopause, with symptoms such as edema, emotional disturbances, blood clotting problems, and allergy symptoms. I think this misconception, that progesterone is "the luteal phase hormone," rather than the often deficient protective hormone, is what caused Dr. Truss to warn against its use in candidiasis patients. (Since most doctors prescribe synthetic progestins, with estrogenic and androgenic side effects, instead of natural progesterone, Truss's warning has probably helped some

women to escape that maltreatment.) Because of its effects on IgA, on blood sugar and the allergic reaction, and on the body's response to stress, natural progesterone would seem to be one of the most useful materials in treating candidiasis.

In the fungi which respond to the human sex steroids, these hormones function as sex hormones, or as sex pheromones—they attract the appropriate cell type, while causing changes in the cells which prepare them for conjugation.

In cell culture, virulent strains of Candida were found to adhere to cells from human membranes, while non-virulent strains didn't adhere. Also, the virulent forms of yeast adhered to cells taken from some people, and didn't stick to cells from other people. Even *in vitro* vaginal epithelial cells were more attractive to Candida—more yeasts adhered—when cells were from diabetics, pregnant women, or women near menstruation. This strongly suggests that glucose is not the regulating factor, since the glucose would be standardized in the culture fluid. More likely factors are estrogen, cortisone, the absence of an iron binding protein, or of bound antibodies; hypoxia causes increased cellular concentration of free fatty acids, so this is another possible factor.

The obvious next experiment will be to pretreat both yeast and donor cells with estrogens and other hormones including cortisone and testosterone, to see if virulence can be induced.

Estrogen and cortisone are things which suppress the host's immunity, and which appear to modify the fungus. Two other things, which have interesting connections with estrogen, can suppress immunity and stimulate yeast growth: unsaturated fatty acids and excess iron. Diamond has suggested that the reason candidiasis often occurs in leukemia is the high iron level in that disease; others have suggested that leukemia itself might be caused by an excess of iron, blocking the immune system. Iron (and high levels of zinc, i.e., 10 mM) stimulate the formation of mycelia (Hazen and Cutler, 1983).

In a low oxygen environment, unsaturated fatty acids can stimulate yeast growth,[4] and they suppress immunity in various ways.

Besides a direct effect on cellular immunity, unsaturated fatty acids interfere with thyroid function and with mitochondrial respiration. Low thyroid leads to high estrogen. Estrogen (and low thyroid) cause increased absorption of iron. At an extreme point, excess iron disturbs several endocrine glands, but at a more moderate level, it blocks cellular

immunity. Combined with unsaturated fatty acids, iron stimulates peroxidation, with toxic effects, including the formation of carbon monoxide, inhibiting respiration. Vitamin C stimulates the absorption of iron, and can also increase the rate of peroxide formation. In a special disease of iron retention, idiopathic hemochromatosis, vitamin C was found not to increase iron excretion when tested by itself, though it did increase the effect of a drug called deferrioxamine.[5]

The mitochondria are not only the site of respiratory energy production, but are where cholesterol is converted to pregnenolone, which is then converted to progesterone and DHEA. These steroids all appear to protect the respiratory system. This respiratory protection is probably part of what Selye called the "catatoxic" function, the fact that certain steroids, especially pregnenolone, protect organisms against a great variety of poisons.

Whether it is an exogenous chemical, or a poison produced by intestinal organisms, or a toxic effect of damage to one's own tissue, which is making a person sick, it would seem reasonable to use a protective, "catatoxic" material such as pregnenolone as part of the supportive therapy. Fiber, oxygen drinks, and aspirin can protect the bowel.

My first experiments with yeast were with the Koch reagents, but then I got interested in testing possible anti-iron substances. Caffeine, I suspect, uses that mechanism, among others. I have also experimented with essential oils, clove oil, thymol, and menthol, and elemental sulfur, which is probably the least toxic therapy for many fungus infections of the skin, vagina, and bowel. Lime-sulfur and other sulfur mixtures have a long history as fungicides. Saturated fatty acids generally inhibit fungal growth. Short chain acids, such as acetic, lactic, propionic, and caprylic acids have often been used as anti-fungals, and even the longer chain saturated fatty acids have been tested.

Large doses of vitamin A and potassium iodide have been used, separately and together, to promote general immunity, and also to treat fungus infections; I suspect that an effect of the iodide is to protect against the toxicity of the unsaturated fatty acids.

Thiosulphate is another form of sulfur that has been used for skin fungal infections. Many herbal drugs contain quinones and saponins which are active against fungi, but which can be dangerous to the patient. The imidazoles can be dangerous because they block steroid synthesis in the patient as well as in the fungus. Nystatin is also believed to act

on fungal steroids, and it can be toxic to the patient, but it is considered the best treatment for a deadly systemic infection (e.g., lungs, heart, kidneys). Desensitization with Candida vaccine and treatment with immune rabbit serum are discussed in R. Dubos's book, *Bacterial and Mycotic Infections of Man*. Boric acid (5 %), antihistamines, and many other chemicals have some anti-fungal activity, but except for sulfur, I think the best approach is to optimize the patient's resistance.

Inhibition and Vitality

Townsend Letter for Doctors, February, 1986

In the Achilles reflex test, slow relaxation of the calf muscle is used to demonstrate the low metabolism of hypothyroidism. In the high energy person, relaxation is instantaneous. This is a general principle for the brain and other tissues: the high energy state is relaxed.

Epilepsy is an example of a very low energy state of brain cells. Insomnia is a low energy state, and is usually cured by the right dose of thyroid hormone, with adequate glucose and other nutrients. Insomnia is extremely common in aging people, and is the main problem at menopause. Inflammation is another example of a low energy state. Specific patterns of symptoms can be produced by reflexes, and these reflexes can be stuck in place by an energy deficiency. Focused activity and an alert readiness to respond are prevented by a low energy state, which can cause us to get stuck in inappropriate activity, ranging from worry to "auto-immune" conditions.

The inhibited state of nerves has not been a popular field for research in our culture, but the knowledge gradually accumulates. Another type of inhibition has been described recently by Egan and North.[1]

Burton

Last year the Center for Disease Control tested some of Dr. Burton's immuno-augmentative therapeutic material, and found that 50 % of it was contaminated with AIDS virus (at least the antibodies), and that all of it tested positive for hepatitis. Since he had been getting all of his blood from the U.S., from commercial sources, this sounded suspicious.

In the 1960s he was highly respected. The year he got in trouble, 1975, was the year the cancer establishment decided to follow his leads in immunotherapy. Dr. Coley's toxins were removed from the "quack remedy" list. Last year, when Burton's institution was closed down because of the incredibly high rate of AIDS contamination, was the year that the biggest institutional researchers began their promotion of the tumor necrosis factor—which Burton discovered.

Burton used a variety of blood-derived materials, but purification will be necessary before a drug company can control it satisfactorily.

If the stuff doesn't kill people, along with the cancer, it also has great financial potential as a weight-loss drug. I have been trying to learn his side of the contamination story, so I recently tried calling his 800 number, but I was too late, and the woman who answered said she had no knowledge of his organization; she just worked for the U.S. Army. If you know his address, please let me know.

Black Body Radiation

A red hot object radiates lower energy, longer waves than a very hot star does, and a warm person radiates slightly longer, lower energy waves than does the red hot object. The peak of our radiant emission is long infrared, and we are fairly transparent to that wavelength, so we are black body emitters, regardless of our skin color. It has been calculated that 70 % of our metabolic energy is spent as radiation.

If we are surrounded by large amounts of mass at our own temperature, we will absorb about as much as we lose. Several years ago, lab rats were kept at a constant temperature, with constant 12 hour light periods, and were found to experience a decline in thyroid function during the winter. I had noticed a similar effect in hamsters, atrophy of the thymus gland in the late autumn. Since long-wave infrared and longer wavelength microwaves can penetrate walls to some extent, it could be that the absence of that kind of radiation during the winter is the stressor which causes these changes, and the mitochondrial damage which occurs in the winter.

It could be that some of the therapeutic effects of natural hot springs are caused by gently appropriate radiation from the large masses of hot earth in the vicinity. I think these longer waves might also have an anti-free radical effect, possibly by acting on solvated electrons.

Forests

In the early 1950s I went back to a stream I had seen a couple of years earlier, in southern Oregon; it was one of the most beautiful places I had seen. On my second visit, it had been absolutely destroyed by loggers, who had bulldozed earth, broken logs, and rocks into it. It was just one of the many small streams where fish used to spawn, that have now been destroyed by loggers. A forester has said that much of southern Oregon

will never be able to grow forests again, because the soil was eroded after the trees were cut.

A recent news item mentioned that the Atacama desert in Chile also used to be a humid coastal forest, and that it was destroyed by loggers. Another news item mentioned that removal of trees from the Mexican hill where the Monarch butterflies migrate for the winter was lowering the humidity to such an extent that the butterflies might not be able to survive, even though their own trees are not removed. This effect of trees on humidity is very important, but it is usually overlooked. The concept of "desertification" is widely accepted when it is applied to another continent (the Sudan, for example), but not when it might relate to a local resource which supports the area's biggest industry.

When I first went to Mexico in 1955, I was shocked by the huge gullies that were being eroded through the dark brown soil of the hilly grass-covered expanses in the western part of the State of Mexico. In later years those sharp cuts through the muddy earth had disappeared, and a smooth contour had returned, but the remaining soil was pale and rocky, and barely supported grass. A few years ago I learned that this region had been covered by the same dense pine forests which still exist in some parts of the State, but that a foreign company had removed the forests early in this century. A place there is still called El Yukon.

Now that most of the forests, from the California redwoods into Washington, have been destroyed, the center of the logging industry has moved north into Canada. Foresters describe the logging technique used there as "extraction," and say it won't be long until their forests are depleted, so that maybe Oregon's forests will regain their competitive position. Canada's Yukon might someday resemble El Yukon in Mexico.

When a region doesn't go directly from a conifer forest to a desert, it may be replaced by deciduous shrubs and trees. The ultimate outcome of this replacement is unknown, but I think we are already seeing some of the effects. Conifers are good at conserving water: they transpire sparingly in the hot, normally dry summers of the Pacific coast region, but they do transpire a little in the winter. Humid air is lighter than dry air: a massive forest allows ocean air to circulate over the land in winter, yet a conifer forest does not extravagantly increase the humidity in the summer. A deciduous forest, leafless in winter, allows dense cold dry air to accumulate, which diverts the humid ocean air. In the summer, however, their intense transpiration tends to intensify the entry of air

from the ocean, with the result that rainfall tends to become seasonally reversed, and some of the winter moisture is dumped further south.

People who defend the lumber industry's practices say that the forces controlling weather are too big to be influenced by human activity, but several studies show otherwise. For example, the absence of vegetation in the city of St. Louis causes such intense summer heating and updrafts that corn production has doubled in an area down-wind, from the resulting increase in the summer rainfall.

Caffeine

A study in Israel, where there has been no publicity about a connection between caffeine and breast disease, found that using caffeine or avoiding it had no effect on breast disease. A letter in *JAMA*[2] says "most reports show no significant correlation between fibrocystic disease and methylxanthine intake." He says "there was considerable evidence to suggest that caffeine has antineoplastic effects." He also says that "caffeine intake had a significant association with tumor differentiation…Since poor tumor differentiation is linked with decreased survival, the question is raised whether caffeine may have had a beneficial effect in these women." All of the experiments in cell culture similarly suggest that caffeine might be beneficial.

Cystic Fibrosis

Several years ago a "mutation" was discovered in a regional primate center which was said to be equivalent to human cystic fibrosis. A researcher there couldn't believe that an identical mutation could have appeared at the same time in five or six apes: he believed that their symptoms resulted from poisoning from the large amounts of unsaturated vegetable oil they were being fed. He was fired immediately: the new "gene" would have brought in large amounts of research money. A recent study of young adults with cystic fibrosis found that they had low serum levels of both selenium and vitamin E. This seems to support the ex-scientist's theory.[3]

Food Radiation

As sulfite is removed from foods, pressure will increase for wider use of radiation to extend shelf life of many foods. Proponents are saying that some public education will be necessary, because radiation causes instantaneous changes which modify flavor and texture of foods, making people think they are not fresh: people must be informed, they say, to realize that the spoiled taste and consistency actually means greater freshness, since their shelf life has been extended by many weeks.

Radiation, of course, stimulates oxidation of fats, among other changes (called "unique radiolytic products," URP), and rancid fat is toxic and carcinogenic.

Insomnia & Hyperactivity

Townsend Letter for Doctors, April, 1994

SOMETIME after my teens, I became a light sleeper. I found that if I stayed up too late it was hard for me to go to sleep, and then when I slept it was restless and dream-disturbed sleep. I suspected that my hormonal state was in some way analogous to that of new mothers, who wake at the slightest sound from their infant. A friend of mine had an episode of psychosis after her child was born, and I began to think about the frequent association of post-partum hypothyroidism with emotional or perceptual problems. Although I tended to be hypermetabolic, and had been puzzled for years about the co-existence of signs of both hyper- and hypothyroidism, I finally tried taking thyroid. Immediately, I was able to sleep easily and deeply, and my need for food decreased. It was obvious that thyroid was having a quieting effect on my whole metabolism. I slept more efficiently, woke up refreshed, and had abundant energy during the daylight hours, and began looking for chores to do around the house, just for fun. Before taking thyroid, the first thing I did every morning was to drink two or three cups of coffee, but a few days after taking thyroid I noticed I didn't think about coffee very often, and I drank about 90 % less, without feeling any withdrawal symptoms.

Since the 1960s, a stimulant, Ritalin (methylphenidate) has often been prescribed for hyperactive kids, because it made them able to quietly pay attention. This effect was called "paradoxical," but—for scientific physiology—there was nothing paradoxical about it. The frontal lobes of the brain, the most highly evolved part, give us the ability to plan and to understand complex things that require prolonged attention. Without this higher part of the brain which has a very high energy requirement, people and animals become hyperactive and unable to concentrate. Ritalin (or coffee) makes anyone, even the brightest students, more attentive and focussed. Caffeine and Ritalin temporarily raise the energy level of the brain. Thyroid hormones are essential for providing the energy to keep the brain at a high energy level all the time. If these hormones are deficient, our nerves need stimulants to function normally, and our bodies ordinarily produce large amounts of adrenalin to keep us going. The result is that we get tired and tense at the same time.

An old and useful test of thyroid function uses the Achilles tendon reflex, to observe the relaxation speed of the calf muscle. In hypothyroid states, the muscle is slow to relax, because the cells are slow to replace the energy used by the contraction-twitch. Because of the slow energy production, the muscles tend to fatigue easily, and to swell and feel sore with moderate exercise. In children, painful, swollen and tense muscles sometimes make it hard to go to sleep after an active day.

In the heart, slow replacement of energy can be seen in the EKG, as a delayed and depressed T wave; if this is combined with stress and excitement, it can cause a rhythm disturbance.

The brain is just like muscle, in having to restore its energy to relax. Many people have noticed that eating a lot of carbohydrate and/or salt makes them sleepy. Both salt and carbohydrate tend to lower adrenalin, and carbohydrate can also increase the activity of thyroid hormone, while restoring energy to the tissues.

In the last 20 years, I have seen almost everyone's insomnia disappear when they correct their hypothyroidism, sometimes just with dietary changes, but more often with a thyroid supplement. Many times, people have told me that they get to sleep within a few minutes when they take a minimal dose of thyroid at bedtime. By increasing the rate of energy production, relaxation and sleep are made possible.

In 1973 (in my book, *Mind and Tissue*) I reviewed old studies of cellular inhibition, which distinguished between the naturally quiet resting state of energized cells, and the state of protective inhibition, which prevents injury or death from overstimulation and fatigue. In our "establishment physiology," there has been no coherent theory of cellular inhibition, which means that cellular activity could hardly be understood correctly, either. Most of the facts are known, but they have seldom been put together in meaningful patterns, which would let us see that a few simple principles govern a great range of disturbing phenomena: seizures, shock, hypertension, fibrillation, cramps, restless legs, coma, insomnia, obsessive thinking, migraine, hyperactivity, even cell death and aging.

Coherent theories have been rejected because they don't suit the dogma of the establishment physiologists, who like to explain things in terms of hypothetical "membrane pumps." A few fetish ideas dominate physiology, just as the gene and virus fetishes have governed cancer research. For more than a century, most physiologists have "explained"

muscle soreness as being "caused by lactic acid," while generally ignoring the great swelling of muscles that results from intense exercise. When cells don't have enough energy—whether from inadequate fuel, overwork, lack of oxygen, or poisoning—they take up water. Too much water tends to excite the cells, and can even stimulate cell division. The hyperactive state of a muscle cell, cramping, causes energy to be spent. What is too often overlooked is that the cell needs more energy to get back into its resting state, and that an abundance of glucose or other fuel, oxygen, and thyroid are needed for the cell to produce energy fast enough to become quietly relaxed.

Albert Szent-Györgyi demonstrated that rigor mortis, the stiffening of the body that occurs after death, is just an energy deficiency, like a final cramp: he injected ATP (the tissue "energy molecule") into a stiff animal, and its tissues' softness was restored. The idea of "membrane pumps" keeps many people from seeing the implications of experiments like that. Intravenous injection of ATP cures shock, restoring normal circulation and tissue function, but again, the idea of membranes and their pumps has kept mainline science on its relatively sterile track.

The reluctance to see something as simple as the swelling of a muscle when its energy is depleted, has led into other unnecessary confusions. For example, the water that the muscle takes up comes from the blood. The blood gets thicker, and is harder to pump. The loss of water from the blood makes it seem that hormones have increased, when actually they may have decreased. If the tissues could be re-energized, they would release some of their water back to the blood.

For many years, a few physicians have known about the quieting effects of thyroid, and have prescribed it for hyperactive kids, as well as for lethargic ones, and for otherwise healthy kids with "growing pains." Since the mid-1950s, there has been a terrible increase in the incidence of hyperactivity in children, as discussed by Tom Brewer, largely because of prenatal injury. The increased use of unsaturated vegetable oils (proven to cause brain damage in rats) has certainly played a role. The more unsaturated an oil is, the more strongly it interferes with thyroid secretion, the transport of thyroid hormone in the blood, and the response of the tissue thyroid receptors. Hypothyroidism, both prenatally and during childhood, severely limits development of the brain.

It is a simple fact that nerve cells must have an abundance of energy if they are to be able to relax. Every physician knows about the convulsions produced by extreme hypoglycemia, and some know that a lack of oxygen can produce convulsion, but few realize that a high energy state is needed for stable nervous relaxation. Otherwise, no one would hesitate to use thyroid hormone (and its energy-associated co-factor, magnesium) for insomnia, hyperactivity, and the whole range of energy-related problems.

(Incidentally, thyroxine alone can be counter-productive, by competing with the respiration-promoting triiodothyronine, and by suppressing TSH secretion even when T_3 is deficient. Similarly, a normal or high level of thyroxine in the blood doesn't mean that the person isn't hypothyroid, since T_3 is the active hormone. Most of our T_3 is produced in the liver.)

Iodine Injections

Townsend Letter for Doctors, October, 1986

YOU mentioned in the July *Letter* that iodine injectors have been used in atherosclerosis. An old PDR described the use of iodide in atherosclerosis. Could you tell me who has studied the iodine injections? I liked your comments on chelation.

Iron: Cumulative Danger

Townsend Letter for Doctors, June, 1997

Q: You believe iron is a deadly substance. Why?

Iron is a potentially toxic heavy metal. In excess, it can cause cancer, heart disease, and other illnesses.

Q: Could you tell us about some of these studies?

In the 1960s the World Health Organization found that when iron supplements were given to anemic people in Africa, there was a great increase in the death rate from infectious diseases, especially malaria.

Around the same time, research began to show that the regulation of iron is a central function of the immune system, and that this seems to have evolved because iron is a basic requirement for the survival and growth of cells of all types, including bacteria, parasites, and cancer. The pioneer researcher in the role of iron in immunity believed that an excess of dietary iron contributed to the development of leukemia and lymphatic cancers.

For about 50 years, it has been known that blood transfusions damage immunity, and excess iron has been suspected to be one of the causes for this. People who regularly donate blood, on the other hand, have often been found to be healthier than non-donors, and healthier than they were before they began donating.

Just like lead, mercury, cadmium, nickel, manganese and other heavy metals, stored iron produces destructive free radicals. The harmful effects of iron-produced free radicals are practically indistinguishable from those caused by exposure to X-rays and gamma rays; both accelerate the accumulation of age-pigment and other signs of aging. Excess iron is a crucial element in the transformation of stress into tissue damage by free radicals.

In one of Hans Selye's pioneering studies, he found that he could experimentally produce a form of scleroderma (hardening of the skin) in animals by administering large doses of iron, followed by a minor stress. He could prevent the development of the condition by giving

the animals large doses of vitamin E, suggesting that the condition was produced by iron's oxidative actions.

Many recent studies show that iron is involved in degenerative brain diseases, such as Parkinson's, ALS (Lou Gehrig's disease), Huntington's chorea, and Alzheimer's disease. Iron is now believed to have a role in skin aging, atherosclerosis, and cataracts of the lenses of the eyes, largely through its formation of the "age pigment."

Q: How does excess iron accelerate our aging process?

During aging, our tissues tend to store an excess of iron. There is remarkably close association between the amount of iron stored in our tissues and the risk of death from cancer, heart disease, or from all causes. This relationship between iron and death rate exists even during childhood, but the curve is downward until the age of 12, and then it rises steadily until death. The shape of this curve, representing the iron burden, is amazingly similar to the curves representing the rate of death in general, and the rate of death from cancer. There is no other relationship in biology that I know of that has this peculiar shape, with its minimum at the age of 12, and its maximum in old age at the time of death.

One of the major lines of aging research, going back to the early part of this century, was based on the accumulation of brown material in the tissues known as "age-pigment." The technical name for this material, "lipofuscin," means "fatty brown stuff." In the 1960s, the "free radical theory" of aging was introduced by Denham Harman, and this theory has converged with the age-pigment theory, since we now know that the age-pigment is an oxidized mass of unsaturated fat and iron, formed by uncontrolled free radicals. Until a few years ago, these ideas were accepted by only a few researchers, but now practically every doctor in the country accepts that free radicals are important in the aging process.

A nutrition researcher in San Diego suspected that the life-extending effects of calorie restriction might be the result of a decreased intake of toxins. He removed the toxic heavy metals from foods, and found that the animals which ate a normal amount of food lived as long as

the semi-starved animals. Recently, the iron content of food has been identified as the major life-shortening factor, rather than the calories.[1]

Q: Exactly how much iron do we need to eat?

Children's nutritional requirements are high, because they are growing but there are indications that in the U.S. even children eat too much iron. Some researchers are concerned that the iron added to cereals is contributing to the incidence of leukemia and cancer of the lymphatic tissues in children.[2] During the time of rapid growth, children are less likely than adults to store too much iron. At birth, they have a large amount of stored iron, and this decreases as they "grow into it." It is after puberty, when growth slows and the sex hormones are high, that the storage of iron increases.[3]

In a study of the "malnourished" children of migrant fruit pickers in California, these children who were "seriously anemic" were actually more resistant to infectious diseases than were the "well-nourished" middle class children in the same region.

If the normal amount of dietary iron causes an increased susceptibility to infections even in children, and if a subnormal amount of iron slows the aging process, I think we are going to have to reconsider our ideas of nutritional adequacy, to look at the long range effects of diet, as well as the immediate effects. My current studies have to do with analyzing our ability to handle stress safely, in relation to our diet. I believe our nutritional recommendations for iron have to be revised sharply downward.

Q: Don't women need extra iron?

That's a misunderstanding.

Doctors generally don't realize that only a few milligrams of iron are lost each day in menstruation. The real issue is that you can hardly avoid getting iron, even when you try.

Women absorb iron much more efficiently than men do. From a similar meal, women will normally absorb three times as much iron as men do. When pregnant, their higher estrogen levels cause them to absorb about nine times as much as men. Every time a woman menstruates, she loses a little iron, so that by the age of 50 she is likely

to have less iron stored in her tissues than a man does at the same age, but by the age of 65 women generally have as much excess iron in their tissues as men do. (During those 15 years, women seem to store iron at a faster rate than men do, probably because they have more estrogen.) At this age their risk of dying from a heart attack is the same as that of men.

Some women who menstruate can donate blood regularly without showing any tendency to become anemic,

Since the custom of giving large iron supplements to pregnant women has been established, there has been an increase in jaundice of the newborn. It has been observed that women who didn't take iron supplements during pregnancy have healthy babies that don't develop jaundice. I have suggested that this could be because they haven't been poisoned by iron. Those supplements could also be a factor in the increased incidence of childhood cancer.

Q: Don't you need iron supplements if you are anemic?

In general, no.

Many doctors think of anemia as necessarily indicating an iron deficiency, but that isn't correct. One-hundred years ago, it was customary to prescribe arsenic for anemia, and it worked to stimulate the formation of more red blood cells. The fact that arsenic, or iron, or other toxic material stimulates the formation of red blood cells doesn't indicate a "deficiency" of the toxin, but simply indicates that the body responds to a variety of harmful factors by speeding its production of blood cells.

Even radiation can have this kind of stimulating effect, because growth is a natural reaction to injury. Between 1920 and 1950, it was common to think of "nutritional growth factors" as being the same as vitamins, but since then it has become common to use known toxins to stimulate the growth of farm animals, and as a result, it has been more difficult to define the essential nutrients. The optimal nutritional intake is now more often considered in terms of resistance to disease, longevity or rate of aging, and even mental ability.

An excess of iron, by destroying vitamin E and oxidizing the unsaturated fats in red blood cells, can contribute to hemolytic anemia, in which red cells are so fragile that they break down too fast.

In aging, red cells break down faster, increasing the tendency to become anemic, but additional iron tends to be more dangerous for older people.

Anemia in women is caused most often by a thyroid deficiency, or by various nutritional deficiencies.

Estrogen (even in animals that don't menstruate) causes dilution of the blood, so that it is normal for females to have lower hemoglobin than males.

Q: What should I do if my doctor tells me I'm anemic? Is there any situation in which a person needs to take iron supplements?

Iron deficiency anemia does exist, in laboratory situations and in some cases of chronic bleeding, but I believe it should be the last-suspected cause of anemia, instead of the first. It should be considered as a possible cause of anemia only when very specific blood tests show an abnormally low degree of iron saturation of certain proteins.

Usually, physicians consider the amount of hemoglobin or of red cells in the blood as the primary indicator of a need for iron, but that just isn't biologically reasonable.

If a large amount of blood is lost in surgery, a temporary anemia might be produced, but even then it would be best to know whether the iron stores are really depleted before deciding whether an iron supplement would be reasonable. Liver (or even a water extract of wheat germ) can supply as much iron as would be given as a pill, and is safer.

Q: What foods contain iron?

Flour, pasta, etc., almost always contain iron which has been artificially added as ferrous sulfate, because of a federal law. Meats, grains, eggs, and vegetables naturally contain large amounts of iron. A few years ago, someone demonstrated that they could pick up a certain breakfast cereal with a magnet, because of the added iron.

Black olives contain iron, which is used as a coloring material. You should look for "ferrous" or "ferric" or "iron" on the label, and avoid foods with any added iron. Many labels list "reduced iron," meaning

that iron is added in the ferrous form, which is very reactive and easily absorbed.

Q: Why does federal law require the addition of iron to those foods?

Industrially processed grains have most of the nutrients, such as vitamin E, the B vitamins, manganese, magnesium, etc., removed to improve the products' shelf life and efficiency of processing, and the government required that certain nutrients be added to them as a measure to protect the public's health. But the supplementation did not reflect the best science even when it was first made law, since food industry lobbyists managed to impose compromises that led to the use of the cheapest chemicals, rather than those that offered the greatest health benefits.

For example, studies of processed animal food had demonstrated that the addition of iron (as the highly reactive form, ferrous sulfate, which happens to be cheap and easy to handle) created disease in animals, by destroying vitamins in the food. You should read the label of ingredients and avoid products that contain added iron, when possible.

Q: Can cooking in an iron frying pan put iron into food?

Yes, especially if the food is acidic, as many sauces are. The added iron will destroy vitamins in the food, besides being potentially toxic in itself.

Q: What about aluminum?

Aluminum and iron react similarly in cells and are suspected causes of Alzheimer's disease.

The aluminum industry started propagandizing more than 50 years ago about the "safety" of aluminum utensils, claiming that practically none of the toxic metal gets into the food. Recent research showed

that coffee percolated in an aluminum pot contained a large amount of dissolved aluminum, because of coffee's acidity.

Q: What kinds of cooking pots or utensils are safe?

Glass utensils are safe, and certain kinds of stainless steel are safe, because their iron is relatively insoluble. Teflon-coated pans are safe unless they are chipped.

Q: How do I know which stainless steels are safe?

There are two main types of stainless steel, magnetic and nonmagnetic. The nonmagnetic form has a very high nickel content, and nickel is allergenic and carcinogenic. It is much more toxic than iron or aluminum. You can use a little "refrigerator magnet" to test your pans. The magnet will stick firmly to the safer type of pan.

Q: Why is there iron in most multi-vitamin and mineral products?

Although several researchers have demonstrated that iron destroys vitamins, there is enough wishful thinking in industry, government, and the consuming public, that such mistakes can go on for generations before anyone can mobilize the resources to bring the truth to the public.

Ten years ago, I thought it was a hopeful sign of increased awareness of iron's danger when the manufacturer of a new iron product mentioned in the Physician's Desk Reference that it hadn't yet been reported to cause cancer.

Q: I can't avoid all those foods, especially the bread and grains. What can I do to keep the iron I ingest from harming me?

Iron destroys vitamin E, so vitamin E should be taken as a supplement. It shouldn't be taken at the same time as the iron-contaminated food, because iron reacts with it in the stomach. About 100 mg per day is adequate, though our requirement increases with age, as our tissue iron stores increase.

Coffee, when taken with food, strongly inhibits the absorption of iron, so I always try to drink coffee with meat.

Decreasing your consumption of unsaturated fats makes the iron less harmful.

Vitamin C stimulates the absorption of iron, so it might be good idea to avoid drinking orange juice at the same meal with iron-rich foods.

A deficiency of copper causes our tissues to retain an excess of iron, so foods such as shrimp and oysters which contain abundant copper should be used regularly.

Q: How does copper help us?

Copper is the crucial element for producing the color in hair and skin, for maintaining the elasticity of skin and blood vessels, for protecting against certain types of free radical, and especially for allowing us to use oxygen properly for the production of biological energy. It is also necessary for the normal functioning of certain nerve cells (substantia nigra) whose degeneration is involved in Parkinson's disease. The shape and texture of hair as well as its color, can change in a copper deficiency.

Too much iron can block our absorption of copper, and too little copper makes us store too much iron. With aging, our tissues lose copper as they store excess iron. Because of those changes, we need more vitamin E as we age.

Summary

1. Iron is a potentially toxic heavy metal; an excess can cause cancer, heart disease, and other illnesses.
2. Other heavy metals, including lead and aluminum are toxic; pans and dishes should be chosen carefully.
3. Iron causes cell aging.
4. Drinking coffee with iron-rich foods can reduce iron's toxic effects.
5. Use shrimp and oysters, etc., to prevent the copper deficiency which leads to excess storage of iron.
6. Avoid food supplements which contain iron.
7. Take about 100 units of vitamin E daily; your vitamin E requirement increases with your iron consumption.

Notes

A Finnish study, two years ago indicated that high iron stores may increase heart attack risk.[4] Dr. Jerome L. Sullivan, director of clinical labs of Veterans Affairs Medical Center at Charleston, South Carolina, in 1983 proposed that excess iron contributes to heart attacks. University of Kuopio in Finland: Large-scale study (nearly 2,000 men, for up to five years); next to smoking, excess stored iron is the most significant identifiable risk factor for heart attacks. It is a stronger risk factor for heart attack than high blood pressure and cholesterol.

U.S. studies showed a weak connection between iron and heart disease,[5] and a weak connection with the iron in red meat. Epidemiologists at the Pacific Northwest Laboratory in Washington have reported that the greater the concentration of iron in a person's blood, the greater his or her risk of cancer. Richard Stevens and his co-workers found the connection from examining cancer rates in more than 8,000 people who participated in the 1971 National Health and Nutrition Examination survey. A second Finnish study with similar findings accompanied Steven's report in the *International Journal of Cancer*, and suggests that there may be cause for concern.

Associated Press: 1982-92, heart disease death rate dropped 24.5 %; number of cases of congestive heart failure doubled during roughly the same period. It killed 39,000 Americans in 1991, costs system $40 billion per year. Cancer is the biggest killer of women under 64, heart disease far surpasses cancer in women of ages 65–84.[6]

Moles, DHEA, etc.

Ray Peat's Newsletter, 2015

EVERYONE knows what a mole is, but no one understands what a mole really is. Moles are interesting because they are simultaneously normal and a little abnormal. But it seems that no one has taken them seriously enough to study them very scientifically. At least, I don't know of any publications on "the epidemiology of moles," or "the experimental production of moles."

Advertisements from the cancer society fundraisers have taught people that "any change" in a mole could be a sign of cancer. The idea seems reasonable enough, but I think it has no clear scientific basis The fear of cancer has caused many people to have things excised as soon as they are noticed, but during this generation in which people have learned to have things cut out promptly, the incidence of melanoma has risen sharply. Melanoma first appears in normal-looking skin about as often as it does in pigmented moles, so the "preventive" removal of all moles is no guarantee that you won't get melanoma.

At least some pigment cells are "amoeboid," meaning that they can creep around. At body temperature, white blood cells under the microscope can walk about two inches per day.[1] These facts indicate that it could be seriously misleading to think of a bit of tissue, such as a mole, as a "strictly localized" thing, the removal of which has no meaning for the rest of the body.

I will just briefly mention some of the observations that have made me think of moles as "systemic phenomena."

A friend had many protuberant moles that had been present for most of her life (if not since birth), and one summer they withered, dried up, and fell off. She was taking a little more thyroid and triiodothyronine that summer.

One hot summer, I had a four ounce glass of Modelo beer, discovered I liked it, and for the rest of the summer I would often drink a similar small amount during he hot part of the day, while at my friend's house to water the plants. Two moles appeared on my forehead, and grew rapidly, until the bigger one was the size of a small pea. When the beer in the refrigerator was gone, the summer was nearly over, and I had thought increasingly about the estrogen content of beer, so I didn't drink any

more. Within about a week, the moles were shrinking. The smaller one disappeared while the other one was still about the size of match-head. After about three weeks, the remaining mole was about the size of a dried pea, and one morning it rolled free when I touched it. It had become firm and dry.

DHEA Changes Moles

In 1980, a familiar old mole on my belly had begun growing and darkening. A couple of times when I had my shirt off on a hot day physician friends looked worried when they saw it and told me I'd better have it removed. It became thoroughly black, took on a sharply triangular shape, and had a firm leathery texture. By 1981, it was about 15 mm long, but still fairly flat. I had been experimenting with oral doses of DHEA in oil for two or three weeks, and had noticed that it made me feel like an adolescent, but it was causing me to get pimples.

One night as I was going to bed, I looked down and was shocked to see what looked like a maraschino cherry on my belly. I spontaneously flicked at it with my finger, thinking it might be an engorged tick, though the color and gloss weren't appropriate. Just before the second flick brushed it, I too late saw something black on the top of the globe, and realized that it was my mole. The black material brushed away, leaving a small drop of blood, but the dome remained glossy and red. By the next day, it was smaller and was no longer shiny from internal pressure. That afternoon I photographed it, and there was a red flare surrounding it, about 2 inches in diameter. By the third day, I could see that the deflating thing was going to be a brown mole, of roughly the same size as the original one that had been there a few years earlier. The only difference from its earlier state is that its margin might be more diffuse now.

In his mid-50s, my brother mentioned that he was getting a mole-like spot on his forehead. When I told him about my experience, and that I thought oral DHEA might have been responsible for the mole's disappearance, he applied a concentrated solution of DHEA in vitamin E directly onto the mole. A day or two later, he noticed a spot of blood on his pillow, and had his doctor cut the thing off, because of fear that bleeding signalled a malignant change.

After I found that a copper solution quickly caused my white eyebrows to return to their normal color, and repeated the experiment sev-

eral times over about 3 years, I tried the same solution on my sideburns, and saw that some of those hairs had darkened after one application. It wasn't convenient to observe those hairs, so I decided to apply the solution to some white whiskers on my chin. After two or three applications, I carelessly used a solution that was too strong. Within less than a minute I felt it stinging, and washed it off. A stinging sensation was noticeable during the next 2 or 3 h, and I washed the spot thoroughly several times. About 4 h later it was still a little uncomfortable, and when I looked at it in a mirror I was horrified to see what appeared to be a large, coffee-colored mole on my chin, in the area where I had applied the copper, and where the burning sensation persisted. The edges were slightly raised about the surrounding skin, and it looked li ke a normal light brown mole, roughly the size of a nickel.

It was so hard for me to believe that such an anatomical change could have occurred within 4 h that I wondered if I had just failed to observe something that had been developing gradually.

But after about a week it had disappeared, and no trace of it has returned, so I had to conclude that the high concentration of copper had acted with, or in place of, tyrosinase to form new pigment, or that copper-hungry cells had invaded the area.

A couple of years ago I noticed some moles on my upper chest were growing, darkening and developing an irregular, granular form. I hadn't used any DHEA for a few years, just because I had lost interest in it. A friend had just been telling me about using topical progesterone and DHEA in vitamins E and A to shrink a large and growing mole on her leg. For a few weeks I watched carefully as my moles changed since their location made it easy for me to view them at very close range. After becoming nearly black, I noticed that they were fading and becoming sort of grey. Then white and creamy areas appeared, and the grey seemed to concentrate into a few blue spots. The changes were surprisingly fast. I would look at them 2 or 3 times a day, and the blue, or black, or brown spots would be in entirely different locations each time. The moles had become firm to touch, but the spots of pigmented cells appeared to be swimming wildly around within the boundaries of the moles, as if looking f or something, or escaping from something. I smeared a very light film of vitamins A and E with DHEA over the area of my chest with the moles, and the next time I looked the color was becoming regular. Within a day or two, even the texture had returned to normal.

Higher Altitudes Decreases Cancer Incidence

About ten years ago, a cancer geographer mentioned that he had found an inverse relation between altitude and the incidence of cancer around the world. A woman from Texas who was at the conference was sure his information was wrong, because the higher intensity of "radiation" at high altitudes would increase the damage to DNA that is commonly supposed to cause cancer. She decided to disprove his work by doing a study limited to the incidence of melanoma—which is supposed to be especially sensitive to ultraviolet radiation—within Texas. Her results surprised her; even melanoma incidence was lower at higher elevations.

Much of the doctrine about radiation at high altitude has been created by and for the nuclear industry. Actually, the dangerous secondary and tertiary particle showers from cosmic rays are more intense at sea-level than at high altitudes. But the greater oxygen pressure at sea-level might be the most important factor in various kinds of cancer, and other disease, since our antioxidant system can probably maintain better balance at high altitude. Mitochondria become more numerous at high altitude, and this might result from increased durability, as well as from the need for more efficient use of oxygen.

The skin is a major source of sterol formation. Skin changes in aging might indicate a special susceptibility to sterol deficiency, which could make topical application of steroid-associated materials especially appropriate.

About 50 years ago, melanosomes were believed to develop from mitochondria. Whether that was accurate or not, there are some interesting parallels between respiration and pigment metabolism. Copper, vitamin A, pregnenolone, progesterone, vitamin E and DHEA are intimately involved with both. The glucocorticoids tend to antagonize both.

Pigment Cells Related to Nerve Cells

Leghorn chickens are sometimes thought of as genetic albinos, but when relieved of the stress of egg laying, they can form black feather pigment. Domesticated animals of various kinds tend to become white. Soviet fox breeders selected foxes for tameness for 20 years. The foxes bred for tameness also lost their wild coloring, and became spotted.

The migration of pigment cells through the tissues of the developing embryo reflects in some way the altered balance of the whole organism.

It is this distribution of cells during embryonic and fetal development, and later in life, which produces "birth marks" and moles. Pigment cells and nerve cells are closely related in embryonic development, so it is interesting to notice the similar appearance of astrocytes in the brain and melanocytes in the skin.

Macrophages sometimes have a similar structure, and when stained with metals reticular macrophages and astrocytes (both have been called "metalophils") look surprisingly similar.

Metchnikov developed this theory of inflammation and immunity by phagocytosis in connection with his attempt to explain development, how ontogeny reflects—but alters—phylogeny. The recognition and preservation of self, in the immune reactions, was just an aspect of the ontogenetic creation of individuality.

When my phagocytes eat up one of my moles, and a good copy of my "original" mole is reconstituted in the same location, Metchnikov's idea of a dynamic organismic integrity, in which the phagocytes play a central developmental role, takes on new concreteness for me.

In 1983 I noticed that the whiskers on my cheeks were going white in circular as if the melanocytes were migrating centrifugally. Around the same time I noticed a flat mole, or raised freckle, was growing on my temple. Although many people have those spots removed, it is very common for people in their 80s to have a button-like black spot on the temple. My spot waxed and waned, but on average tended to get bigger and darker with the years.

In Mexico recently, a friend found that applying DHEA in vitamin E to a very big, red keloid tumor caused it to quickly fade and shrink. As I was driving home, I applied a little of the same solution to one of the mole on my temple. A day or two later I noticed a concentric ring of brown skin on the opposite side of the mole, about a centimeter away. The next day, there were two such bands. Then a bright red line appeared at the front margin of the mole, where I had first applied the oil. Although it looked as though the edge of the mole had bled, it was actually just a threadlike region of extremely dilated capillaries. Day by day, the thread of red appeared to be contracting around the mole. The brown rings took on a V-shape, and extended into the hair. The color of the mole became lighter for about a week, and as the red thread "contracted" the flat mole became pedunculated and mostly colorless, like a tiny mushroom. Two or three dots of color remained, apparently

trapped, in the globe. After drying and shrinking for a couple of days, it fell off, and the point of attachment had become smooth, normal skin within a day.

In this case, the concentric rings of brown pigment suggested that pigment cells might be returning to their normal locations, after having lived for ten years in an island on my temple. This might suggest that this particular skin area is the last to lose its ability to produce DHEA, and that well-nourished cells can remember where they belong.

Lipofuscin Produced in Oxygen Deprivation

Age pigment, lipofuscin, is produced in oxygen deprivation, apparently from reduced iron which attacks unsaturated fats. It has its own "respiratory" activity, acting as an NADH-oxidase. Melanin is produced by polymerization of amino acids, with copper as the catalyst. With aging, iron tends to replace copper. Melanin is an antioxidant. Thus, there is a sort of reciprocal relationship between the two types of pigment. A vitamin E deficiency relative to consumption of polyunsaturated fats, and an estrogen excess, accelerate the formation of lipofuscin.

A 47 year-old woman who had only a few "liver spots" on the backs of her hands began taking large amounts of estrogen, and within a few months the brown spots had darkened and spread until most of her skin was covered with spots. When she stopped using estrogen, and applied progesterone topically, the spots disappeared.

Since both keratinocytes ("keratinophages") and "melanophages" can phagocytize melanin granules,[2] the occasional rapid disappearance of "age pigment" makes me wonder whether pigment-loving cells can't ingest and destroy lipofuscin. To the extent that lipofuscin wastes oxygen, the phagocytes might be able to relieve some of the symptoms of oxygen deficiency in aging.

(My recent experience with an 82 year-old man with emphysema who regained a normal pink color a few days after beginning to use DHEA and pregnenolone led me to wonder whether the improvement was mainly in the lungs, or in the other tissues.)

If leukocytes can direct organized attacks on moles, with reconstruction of healthier tissue at the same location, the healing of an infection, or a wound, should be seen in the context of growth, construction, and creation, instead of simply attack upon a foreign body.

If leukocytes remove age pigments and deteriorated moles by recognition of an "age antigen," as in their removal of old red blood cells, or the unnecessary tadpole tail in maturing frogs, then we have a way to begin to grasp the mechanism of ontogenic evolution through various stages and "recapitulations of phylogeny," rejecting one structure as another step forward becomes possible. (The fact that the senescence antigen appears in embryonic kidney cells, as well as in adult liver cells, indicates that it has to do with development, the transition from one stage to another, rather than simply with the "wearing out" of cells.)

Melanoma sometimes spontaneously regresses, in a self-digesting manner.[3] This might be the process that I have seen in my "autolytic" moles. The fact that the "tumor necrosis factor" is also a cachexia inducing factor (and is produced by activated macrophages) provides another perspective on the idea that the whole body might be designed to periodically melt-down, to be systematically reconstructed anew.

Mortality Again

Townsend Letter for Doctors, June, 1994

MARIA de Sousa's work on thymus-derived cells and their relation to the body's iron economy has made people aware of the possibility that iron "fortified" flour and other foods might be contributing to the incidence of leukemia and other cancers, and to immunodeficiency resulting from maldistribution of lymphocytes.

"And with the weight of iron advertisements in this country one inevitably starts feeling that it is not going to be easy to tell this community that in some circumstances iron may be bad."

"It is iron and Flintstones, and the food almost all of our Hodgkin's children ate—as we found out from the rough survey of eating, drinking, and living habits."[1]

It was probably the World Health Organization's observation of a high death rate from malaria in people who were given supplementary iron for their "anemia" that made it obvious that iron can have rapid and deadly immunosuppressive effects, though it had long been suspected that an increase in the iron burden was a factor in the immunosuppressive action of blood transfusions. My interest in the toxicity of iron was aroused by the published discovery that, when added to animal food, iron destroys the vitamin E which was also added to the food. Subsequently, it was found to destroy other vitamins, too.

In recent years, the interaction of iron with vitamin C (and other reductants) and unsaturated fats, to produce lipid peroxidation, has been the dominant issue in research on the toxic effects of iron. "Reperfusion injury," any stress causing oxygen depletion and an excessively reduced (electron-rich) cellular state, the importance of lipid peroxidation and iron in aging, and the role of iron in damaging steroid synthesis in steroidogenic tissues, have been important lines of study lately.

Early in the century, the tendency of calcium and iron to be deposited together in damaged tissues was noted, but the exact reason for this association still isn't known. I think iron's role in "age pigment," lipofuscin, is an important part of the mechanism. In oxygen deprivation, heme (the iron-binding oily component of hemoglobin and various enzymes) is produced, largely by spontaneous, non-enzymic means. Age pigment consists mainly of lipid peroxidation products, with heme and iron. It

has the adaptive function of keeping NADH oxidized in a low-oxygen environment, in which mitochondrial respiration is inadequate, allowing NADH to keep the glycolytic sequence operating. It has been found that age pigment is produced in the fetus, because of its low-oxygen environment, and in fish that are living under ice, again because of the low-oxygen environment, which allows iron to become reduced and to catalyze lipid peroxidation. In old age, blood leaving the lungs is often only half saturated with oxygen; the tissues are likely to be overloaded with iron, and it becomes increasingly likely that fat will be mobilized as an energy source.

The other factors besides iron overload and oxygen deprivation which cause premature loading of the tissues with "age pigment" are a diet low in vitamin E and/or high in unsaturated fats, and an excess of estrogen.

Around the time these factors in the formation of age pigment were being investigated, the Shutes were investigating the antagonism between estrogen and vitamin E. Essentially, their antagonism consists of the fact that vitamin E spares oxygen, and that estrogen wastes oxygen.

Women absorb dietary iron about three times as well as men do, but during pregnancy their absorption is about nine times as efficient as men's.

The famous antagonism of molybdenum to copper absorption is similar to that between iron and copper. Copper deficient cells, for example in the heart, become overloaded with iron. Recently, various studies[2] show that cellular oxidative stress promotes iron retention, which would be logical, since iron is essential for respiration, and cells struggling to respire would tend to use evolved mechanisms for retaining the iron needed to form new respiratory enzymes. (As I suggested above, I think spontaneously formed heme is the probable reason for iron's tendency to concentrate in hypoxic tissue.) Estrogen, by creating relative hypoxia, promotes iron retention.

The fetus, a whole organism within an organism, has a special oxygen problem. Fetal hemoglobin, with a great affinity for oxygen, helps it survive in that situation. (I suspect that fetal hemoglobin will reappear whenever there is prolonged hypoxia.)

I believe it is the low oxygen environment which causes the fetus to be born with a great surplus of iron. Prenatally, iron is absorbed about 40 times faster than while the baby is nursing. Although pregnant women absorb iron from food very efficiently, they tend to give up their stored

iron to the baby. This could account for the greater longevity associated with having more babies, and especially with the lower incidence of cancer in child-bearing women.

Milk is remarkably "deficient" in iron, and it seems obvious that this is an adaptive feature, allowing the child to "grow into" the large amount of iron stored in its tissues at birth. I mentioned the fact that iron and calcium both tend to be deposited in damaged and dying tissues. If it is the situational hypoxia of the fetus that causes its prenatal iron overload, we might expect it to be "overloaded" with calcium, too, and that seems to be the case, with the extra calcium being stored in the porous centers of the bones.

Estrogen causes an exaggerated absorption of calcium, as it does of iron, and high calcium diets have been found to be very toxic to pregnant animals. The combination of estrogen and calcium can cause a condition called osteopetrosis, or hardening of the bones, in which the bone-marrow cavity is closed up, severely limiting the production of the cells which would become Natural Killer cells, normally found in the spleen. Estrogen causes a reduction of Natural Killer cells in the spleen, even without destruction of the bone marrow.[3,4]

Estrogen, and a variety of poisons, cause even soft tissues to retain calcium. It is clear that scleroderma, a hardening of the skin, involves the interaction of calcium, iron, lipid peroxidation, and hormones, but lately it

seems that no one wants to think about it physiologically. The food and drug industries have their motives; we are hearing more about drugs to chelate iron and calcium from the body, than about simply leaving iron out of food, or restoring vitamin E and magnesium. And researchers like to aggrandize themselves by making problems seem more complex than they really are. And of course, disease-centered fund-raising organizations always see their business as raising funds, not finding cheap solutions to problems.

At the age of 12, people are less likely to die than at any other age. The curves for mortality from cancer, and from all causes combined, are similarly shaped, with a minimum around the age of 12. The sex hormones tend to stop bone growth, at least in the sense that puberty leads to the hardening of the growth-areas of long bones. When growth stops, the concentration of iron in the tissues tends to increase (even without considering the effect of hormones on iron absorption).

The high mortality of old age is associated with a high concentration of iron in the tissues, just as the high mortality of young infants is associated with a high concentration of iron. As the infant's iron is diluted by growth, mortality decreases.

Infectious disease and leukemia, which have been associated with excess iron, are highest in childhood and old age.

June Goodfield's book gives a nice summing up of the early research on the relation of iron metabolism to cancer and immunodeficiency:

"...in essence the immunological system has evolved with the ability to survey, and recognize, and utilize—I don't know exactly what. But this ability is expressed as a capacity to survey metals and, in particular, iron."

"It goes in as ferrous iron, and is then rapidly oxidized into ferric iron. This is then bound to a protein, transferrin, and so is carried into the bone marrow and thus given to the early red blood cells, which need it for the blood cycles. But iron is also bound to a second protein, ferritin, which is a storage protein...When red cells get old they break down in the spleen and are eaten up by the macrophages, which then make ferritin. (It enters the storage pool again.) Then there is the third protein, lactoferrin, which is synthesized by polymorphs, the white cells, and is present in milk and in our secretions. The amount we excrete per day is absolutely minimal. You can only shove it in; you can't push it out. Now if, for some reason or other, there is too much iron around, the macrophages go and mop it up. And as far as I'm concerned, in the diseases we've been studying—Hodgkin's, leukemias—there is an abnormality in the lymph nodes and the macrophages in regard to the intake, or the handling, of the iron...I have a simple scheme, again probably too simple. Lymphocytes go and are caught where there is an excess of iron. A malignant cell, like a virulent cell, behaves like a virulent bacterium. It becomes capable of sucking up iron avidly and utilizing it...if the tumor cells eat up the signal—iron—the lymphocytes won't go there. The tumor will grow undisturbed because the lymphocytes have not had a signal to move toward it."

As I mentioned above, I think some of the excess iron accumulates in the form of age-pigment, and that this material serves to keep glycolysis running as an emergency energy source. Glycolysis produces lactic acid, which is characteristic of tumor metabolism even in the presence of oxygen, and lactic acid has its own direct effects on immunity.

Americans who eat processed grain products are obliged to eat iron, because of the federal law that they must be "fortified," in spite of the clear evidence that adding iron to food destroys its vitamins. Only public pressure can change this law. Those who have promoted the use of iron fear change, because of their potential liability.

Natural Immunity and Viral Infections

Townsend Letter for Doctors, August/September, 1988

W. F. Koch worked in Moses Gomberg's lab, where free radicals were first observed. Koch soon constructed a theory of natural immunity against virus and cancer, based on his belief in the existence of biological free radicals, able to oxidize virus particles and carcinogenic molecules. Koch believed that allergies were an early sign of the failure of this free radical oxidation system.[1,2]

Albert Szent-Györgyi worked out some of Koch's ideas, and in the process discovered vitamin C (which has a free radical state), and explored many other energy exchange processes, including free radical activation by biological pigments.[3]

Both of these men argued that there is a special interaction between biological structure and the activated electronic state, and that both structural and electronic properties of molecules are involved in their toxic or therapeutic functions.

This model of cell structure and function leads to the expectation that any substance is likely to have a broad range of effects, acting on many different cell types, and promoting or suppressing cell functions, depending on the cell's type and its present state.

In this view, the living material is not an ordinary liquid, but is deeply structured, somewhat like a liquid crystal, and this structure is subject to many physical influences, in the process of adapting to a changing environment.[4]

Newer techniques are letting us visualize more of this finely structured cellular system, and it has been found that many types of virus replicate themselves while attached to the cell mesh-work.[5] Alterations in the mesh-work and the adjoining water will obviously affect the ability of the virus to multiply.

The highest energy states of the cell tend to exclude water soluble substances, and to absorb oil soluble materials. The components of a virus have very specific affinities for water and oil, and they can be assembled only in a very special solvent environment. As mentioned above, a substance which modifies any type of cell will modify others. The high energy state of a cell is an electrically "hyperpolarized" state, and for a nerve cell this is an inhibited, quiet state.

Camphor

There is a long history of anesthetic substances being used to treat viral diseases. Abrams, in a 1910 textbook, described the use of chloroform to cure a viral disease in a horse. Camphor, besides being used as a local anesthetic and a heart stimulant, has been used to treat influenza and other systemic diseases,[6,7] and is one of the oldest topical treatments for herpes sores. More recently, a veterinarian reported curing an "incurable" virus disease in a dog with an anesthetic dose of ether.

Adamantane, which can be extracted from petroleum, is a close structural analog of camphor, and smells like camphor. With the addition of a nitrogen atom, it is water soluble, and is an effective anti-viral agent, and is also widely used in treating Parkinson's disease (its function is cholinolytic),[8] and more recently is being used in preventing withdrawal symptoms in cocaine addiction.[9] It is not metabolized, and does not present the genetic risk that has recently been recognized for other anti-viral agents which disrupt viral DNA.[10]

The fact that the body is well supplied with substances which—at a slightly higher concentration—are anesthetics, and which are depleted by the stresses which predispose to viral infections, suggests that they may normally have a camphor-like anti-viral activity. Some of these substances, the anesthetic steroids, have been found to prevent some viral infections,[11] and they also have a wide range of anti-toxic effects.[12] Pregnenolone, progesterone, DHEA, and pregnanediol are all good candidates as anti-viral drugs, but etiocholanolone—which also produces fever[13]—is the most interesting of the group.

It is well-known that stress, acting mainly through the glucocorticoid hormones, damages immunity by destroying thymus cells. The anesthetic steroids, especially progesterone, normally reduce the need for secretion of cortisol, but also act as a protective buffer against the damaging effects of cortisol.

Although a physiologically balanced amount of cortisol induces enzymes of detoxification, for example in the intestine, an unopposed excess causes destruction of these enzymes, eliminating much of the intestine's barrier function, and leading to allergies.[14] This action of cortisol against the thymus and against the bowel's detoxifying enzymes very likely accounts for the common association of allergies with virus infections. Since cortisol has a destabilizing, pro-convulsant effect on the

nervous system, there are likely to be psychological symptoms—anything from compulsive behavior to depression or seizures—associated with the other chronic conditions.

In the last century, it was observed that digitoxin (a natural steroid derivative) lowered the fever caused by enteritis.[15,16] This is probably another example of a catatoxic function, a protective function common to many steroids, and probably worked by way of stabilizing the detoxifying enzymes and preventing the absorption of endotoxin.[16] Endotoxin is known to destabilize and inactivate the bowel's detoxifying enzymes, just as an overdose of cortisol does.[17]

Biological Erasers

Although it is important to be aware of the deadly effects of chronic, unopposed exposure to cortisol (and estrogen and prolactin), these hormones which cause atrophy and loss of function in various tissues also have a creative function. I have elsewhere called them the biological "erasers," the hormones of new beginnings.[18] In the case of cortisol, it might be useful to compare its effects on tissue cells to the process of winnowing wheat, in which the chaff is blown away while the grain is retained. I think there is a mechanism, as proposed by Meerson, in which a functional load preserves the cells and systems which are needed in the present environment, while idle cells are eliminated or reduced by cortisol's catabolic action.[19] In this view, intermittent exposure to these hormones would improve resistance, but continuing uninterrupted exposure will destroy resistance.

Adequate energy, for example as available glucose, is protective against cortisol-induced catabolism. White blood cells can protect themselves by metabolizing cortisol in the presence of sufficient glucose.[20]

Some of the consequences of stress are not catabolic. When the detoxifying enzymes have been lost, then bowel toxins block other basic enzyme systems, leading for example to slowed protein turnover[21] and decreased activity of superoxide dismutase.[22] The consequent increase of lipid peroxidation will decrease steroid synthesis.[23] Stress also leads to the production of intracellular toxins, including ammonia and carbon monoxide, which tend to perpetuate the blocked state.

Just as with the anesthetic substances which modify the physical state of the cell, retarding viral replication, the oxidative protective

system has several points at which intervention is possible to support detoxification, and to promote protein turnover.

Injecting Enzymes

Although natural promotion of the enzymes which degrade proteins and nucleic acids will help to shift the equilibrium away from virus production, recent research shows that it can be therapeutic to inject enzymes (nucleases, both DNAase and RNAase) which degrade viral nucleic acids.[24] Using labelled enzymes, it has been demonstrated that virus and enzyme can enter the cytoplasm in the same vesicle. In herpetic keratitis, the enzyme is used as drops and also injected under the conjunctiva, and in infectious mononucleosis and viral encephalitis it is injected intramuscularly.[24] In treating a viral paralysis of bees, the enzyme is administered as an aerosol. It was found that treatment increased the viability and productivity of outwardly healthy bees, apparently by curing a latent viral infection.[24]

While W. F. Koch was interested in the body's own oxidative free radical system of destroying toxins and pathogens, he studied several natural quinones found in medicinal plants. Recent work has found that phototoxins extracted from plants can kill mouse-cytomegalovirus without damaging the mouse cells.[25] These researchers selected chemicals which do not disrupt genetic material, recognizing the probability of serious side effects.

Although injected enzymes and plant toxins are safer than some current chemotherapies, the basic approach to controlling viral diseases should be to support natural immunity, by maintaining energy production at a high level, by unblocking and stabilizing the detoxifying enzymes, including mono-oxygenases, proteolytic enzymes, SOD, and nucleases, and by avoiding prolonged catabolic states. Many natural substances are available which promote these ends, without risk.

While this approach supports the known mechanism of the immune system, including protection of thymus cells and activation of the various white cell mechanisms of attack, it has the novel feature of altering cells physically to retard viral assembly, increasing their exposure to nucleases, proteases, and mono-oxygenases; that is, it mobilizes immune processes in cells which are not part of the immune system. By eliminating stress-induced susceptibility, it systematically shifts the balance toward

normal functioning, and away from parasitic diversion of the organism's resources.

Negation

Vision and Acceptance, January 22, 2014

THERE is one concept that has altered my perception of life more than anything I have ever studied. Some people know it as "negation" others as "denial." I have some ideas for future blog posts where I plan on referencing this theme more directly. Before that can happen, I feel negation needs to be explored and contemplated on its own with as little distraction as possible.

For some of you, this may be an introduction to the idea and I take this seriously. So I called in the big guns, someone who has studied the matter much longer than I have and has helped me to deepen my comprehension of it. I present the following to you, Dr. Ray Peat on Negation:

I think the concept is very simple in itself, but the problem is that it implies a cultural criticism that involves everything, biology, physics, politics, epistemology. Contraries, or different perspectives, can interact to eliminate error, in progressing. Negation is a human function that would stop the free advance of life and consciousness, opposing critical questioning and spontaneous understanding. The refusal to discuss a problem, and the many forms of censorship, and legal-economic systems that make whole courses of action impossible, are negations, that have their poisonous effects. Physiology reflects their poison, in all the ramifications of learned helplessness, restraint stress, the carcinogenic effects of work-school-media-religion-government.

Negation excludes or suppresses those complex processes of being, and implants nothing but—at the most—obligation in their place. Undocumented aliens are negated simply, slaves and citizens are negated but with obligations. Religions tell people that their being is immaterial, a ghost that will be o.k. somewhere else forever, if they do their duty now. Having a false consciousness implanted by schools and television, labels and roles take the place of being. A sense of despair and impossibility is right behind the false consciousness.

Our surrounding context of language and culture is constantly distorting and misinterpreting anything which persists in moving toward a more expansive life. Knowledge, a physiological thing, is expansion,

and as such is always clearing away errors; when people identify with error, they see knowledge as the deadly enemy, that must be destroyed.

Blake's idea of the "intellectual fountain" was very different from the attitude of Schopenhauer and Nietzsche (where "Will" or assertion was the fundamental reality). Blake saw it as always flowing into new territory, discovering new things, enlivening the world that's being discovered-created. When the organism is traumatized, it hardens, and stops developing, and wants to impose its moral hardness everywhere; assertiveness is the antithesis of perceptive life, and devises ways to negate it.

In an authoritarian culture, people want you to forget who you are, so they can implant themselves without resistance. Just recognizing your own presence, to attend to them fully, is something they don't expect; it isn't quite like Carl Rogers' therapeutic presence, because it's conditional—your conscious presence is the condition. Being present and able to listen (and question and understand) is receptive and productive, and it can even be disruptive, but it's very different from being assertive, because it's always hoping to open up new possibilities, rather than imposing something carried along from the past. A priest is being assertive when he says you have to take it on faith, a physics professor is being assertive when he won't justify his assumptions—where would physics be if your assumptions had to be plausible beyond a particular culture of physics? Much of their potential imagination has been invested in thinking of ways to keep you from questioning.

Physics, in the 20th century, has taken on the Nietzchean subjectivism, claiming to quantize/digitize everything. There is no digital nature, but assertive subjectivism has effectively written quantization into the constitution of science, and into the shadow of the humanities that remains in the corporate universities. Bits of "knowledge" are sold and hoarded, and people who would show that they are something other than knowledge are treated as vandals and worse—Aaron Swartz, for example.

A Little Boy Lost

> Nought loves another as itself, Nor venerates another so, Nor
> is it possible to thought A greater than itself to know.

'And, father, how can I love you Or any of my brothers more?
I love you like the little bird That picks up crumbs around the door.'

The Priest sat by and heard the child; In trembling zeal he seized his hair, He led him by his little coat, And all admired the priestly care.

And standing on the altar high, 'Lo, what a fiend is here! said he: 'One who sets reason up for judge Of our most holy mystery.'

The weeping child could not be heard, The weeping parents wept in vain: They stripped him to his little shirt, And bound him in an iron chain,

And burned him in a holy place Where many had been burned before; The weeping parents wept in vain. Are such thing done on Albion's shore?

A Poison Tree

I was angry with my friend: I told my wrath, my wrath did end. I was angry with my foe: I told it not, my wrath did grow.

And I watered it in fears, Night and morning with my tears; And I sunned it with smiles, And with soft deceitful wiles.

And it grew both day and night, Till it bore an apple bright. And my foe beheld it shine. And he knew that it was mine,

And into my garden stole When the night had veiled the pole; In the morning glad I see My foe outstretched beneath the tree.

Introduction

Hear the voice of the Bard! Who Present, Past, & Future sees Whose ears have heard, The Holy Word, That walk'd among the ancient trees.

Calling the lapsed Soul And weeping in the evening dew: That might controll. The starry pole; And fallen fallen light renew!

O Earth O Earth return! Arise from out the dewy grass; Night is worn. And the morn Rises from the slumberous mass.

Turn away no more: Why wilt thou turn away The starry floor The watry shore Is giv'n thee till the break of day.

The Voice of the Ancient Bard

Youth of delight come hither. And see the opening morn, Image of truth new born. Doubt is fled & clouds of reason Dark disputes & artful teazing. Folly is an endless maze, Tangled roots perplex her ways. How many have fallen there! They stumble all night over bones of the dead And feel they know not what but care; And wish to lead others when they should be led.

Neutrinos and Long-Range Interactions

Multidisciplinary Research, 1976

WHAT'S implied by "a wave"? Something which undulates, ripples, or waves—something which persists, and undergoes a change which is transitory, but a change in shape and energy which extends both through space and through time. We can perceive such movement because our senses operate with some intrinsic generality. If the action of rippling water is reduced to a series of sets of points, it is meaningless until we restore the wholeness and generality which encompasses those points.

To have a "wave without a medium," as most contemporary physicists believe they must, means to them that we must suspend our materialistic common sense, and believe in an abstract reality. They neglect the possibility that the extension through space, the spatial interactions, might be a property of matter interacting with the light, and they deny the other major possibility, that light could be waves in a medium which fills space. I want to suggest that both of these processes may be operating to different degrees, depending on material conditions.

In place of a medium, the physicists have come to believe in "fields," mathematical expressions of forces, which ultimately exist as distortions of the geometry of space. So they present us with a space which really exists, so that it can have a geometry and be distorted, but which has no properties other than those introduced into it by things and their forces. Waves of "gravity," for example, will influence geometry in a way so that things will move toward each other—they are like signals, indicating to the other object how it should behave. Although most physicists have a perverse love for abstractness, for mathematizing the world and making space into a formal but empty something, this scheme of a space with no properties is potentially fruitful, if we use it only as a starting point to free us of the formalisms of Cartesian and Leibnizian space and time, and if we immediately start filling it up with what we need to account for observed interactions of things.

Some of Reich's apparently most muddled comments about light (e.g., "If 'light' is due to local orgone lumination and does not 'travel through space' at all, it is quite understandable that in the Michelson experiment no phase difference could be observed in the light beams

which were 'sent' in the direction of the ether 'drag' and perpendicular to it") seem to have been intelligent attempts to describe physically what he could directly perceive about the nature of consciousness and perception itself: that it is a "lumination" of the living material in resonance with a "lumination" in the world beyond the organism. A "chemical" illustration of this process is the "resonance of electrons" which makes some molecules act as an electronic unity, rather than as a cluster of individual atoms stuck together.

Bandyopadhyay and Chaudhuri (1971) have described how gravity can be accounted for on the basis of charged particles tending to move into a region where the dielectric constant is greater, by assuming that the dielectric, the "neutrino sea," tends to be associated with matter. A similar effect has been used to separate living cells from dead ones—in pure water, living cells with a high dielectric constant will move toward a concentration of charge. This experiment, incidentally, shows a dielectric moving on a charge gradient and suggests how the neutrino sea would tend to be concentrated around matter. If the "ether" is in fact a "neutrino sea," as Dudley has argued, then this is a very important property: it would not only be "dragged along" with the earth, but its density would change according to the density of ordinary matter in that region, and this would resolve the question of whether Reich's orgone accumulator was a Tesla box which accumulated electrons, or an orgone accumulator—charge would concentrate neutrinos, and vice versa.

It has occurred to me to wonder how quickly this association can be formed: for example, could a lense escape its concentration of ether by moving very rapidly? According to Dudley, the neutrino sea is isotropic, with neutrinos moving at various velocities up to their maximum, which may be the speed of light; if this is so, then maybe some of the slower neutrinos could be escaped from at high speed, like running thru a swarm of annoyed bees.[†] Presumably, a lense's refractive index could be changed slightly by putting it in different environments or by moving it at high speeds. If the field of neutrino concentration reacts quickly, then a kind of mechanical resonance between objects should be possible, in which vibration could be transmitted by fluctuations in the neutrino gradient. Dudley's suggestion that phonons and rotons can interact with the neutrino sea would also imply the possibility of mechanical resonance directly through the ether. Charge oscillations would also presumably cause oscillations of the dielectric medium, the neutrino sea.

At first this seems to be an excessively peculiar idea, and it may seem better just to think of purely electrical interactions, as in the London forces, with electronic fluctuations or protonic fluctuations (Kirkwood). Phonon-electron interactions, for example, are certainly conceivable without assuming an oscillating medium. But it may be that there are "resonant interactions" which don't involve ordinary sound or electromagnetic processes. A fairly large neutrino "resonant domain" in a metal could, for example, absorb waves of radiation in a way consistent with the photoelectric effect.

Reich's observations of lumination in evacuated tubes might result from a process like this: in a corona discharge, air molecules are ionized, and emit light on recombination: in the dielectric, water, salts become highly ionized; high fluxes of neutrinos might provide the dielectric conditions which promote ionization of the gas molecule in the tube, with light caused by recombination. (This is a matter of shifted equilibrium and not of energy—thermal energy, for example, can be adequate. The neutrinos, etc., might provide the energy.)

Some Russians have proposed that the forces involved in psycho-kinesis may be related to gravity, and that these forces may be what makes life possible, and that they may constitute the material form of mental activity. Drs. A. P. Dubrov and V. N. Pushkin are among those who think something like gravity is involved in psycho-kinesis. The people who have been studied in the USSR move things somewhat as if they had a static electrical charge on their hands, but that has been eliminated as the responsible force; one man presses a book between his hands, gradually removes his hands, and keeps the book suspended. Uri Geller, who performs on U.S. television, says he thinks he is directing some kind of energy outside of his body—his most interesting act is bending nails and keys. These various kinds of psycho-kinesis all are consistent with Dudley's postulations regarding the neutrino sea. Also, Uri Geller's in particular recalls Michael Polanyi's studies of bending and breaking forces in metals and crystals; Polanyi explicitly proposed an "excitable ether" in connection with other observations, but nearly all of

† If it takes time to establish resonance, this would happen—but if neutrinos are caught as easily as outrun, there would be no effect. And if force is exerted by the charged matter on the neutrinos, they would no longer be part of the sea, but would be part of that particular material system. (A slight excitation might be the closest kind of coupling between atoms and ether.)

this scientific work was in the field of "long range interactions"—friction, adsorption, breaking, and reaction rates, for example, were studied in ways which revealed the inadequacy of the conventional "crystal lattice" and "atom to atom" ideas of interaction.

If we hold the mystical-mechanist world-view of conventional physics, things like psycho-kinesis have to be subsumed under "conspiracy" or "delusion." Enough people have seen the performances of Boris Yermolayev, Uri Geller, et al., that a theory of "conspiracy and delusion" now has to be treated as a "lunatic fringe" idea.

In outline, the biophysics of neutrinos might be something like this: biological water, being uniquely ordered, could provide extensive systems of "resonant domains" of interaction with the neutrino sea; these crystalline regions would tend to be mutually stabilizing through resonance with each other, the co-ordination might include electronic and electromagnetic interaction, accounting for the tissue "lasing" apparently involved in the observations of Gurwitsch and others; special interactions between organisms and neutrinos should be measurable in various ways, and might account for the "time" effects of N. A. Kozrev, Reich's lumination and many other of his effects, and maybe for the loss of weight that has been observed at the moment of death by various investigators (however, it also seems that loss of order in cellular water would reduce solubility of gases, and cause a measurable weight loss from gas emission at death). If the organism is seen as a kind of lens or pump for the ether, the neutrino sea, then special cases of its interaction would be expected to involve anything which normally depends on "ether excitation": reaction rates, metal bending or breaking, adsorption, crystallization, and nuclear reactions are some processes suggested by the work of Polanyi and Dudley. The effects of "healers" hands on enzyme rates might be a case of this that is already well known. I think there have also been claims about mental effects on crystallization and nuclear fission.

If consciousness itself importantly involves the neutrino sea, then the ether could be an additional channel for perception and communication, that is, a channel for direct resonance between the organism and what it perceives.

On Recycling Placentas, Thyroid Suppression, and Carpal Tunnel

Townsend Letter for Doctors, August/September, 1990

I am glad to see your comment, "Recycling Placentas," in the June issue. More such dialogue between authors and editors could make the magazine more interesting. Last month, I decided to wait to see whether others would comment on Musarella's statements. Since your comments covered many of the points that needed to be made, I'd just like to add some of my other reactions.

Usually, the authors of foolish medical claims at least have the slight virtue of pushing common errors to an absurd extreme, helping to make thoughtful people more conscious of a problem they hadn't been paying attention to. But there are suggestions in Musarella's article that threaten to besmirch good research. I don't know what "Pr." might stand for, but Filatov is grammatically masculine (Filatova would be a woman's name), and in Russian medicine, the phrase "the Russian scientist Filatov" would be assumed to refer to Vladimir Filatov, after whom at least one Filatov Institute has been named. Vladimir Filatov was a pioneer in reconstructive surgery and in corneal transplants from cadavers. He found that corneas transplanted from cadavers that had been kept in cold storage for some time exerted a healing influence on adjacent tissues. He saw similar effects in reconstructive surgery using "tube-flaps" of skin, and concluded that tissues subjected to stressful conditions formed substances which promoted healing and regeneration. (Succinic acid and other dicarboxylic acids were identified among the "biogenic tissue stimulators." Succinate stimulates respiration and steroid formation, and protects against peroxidative damage. Filatov's work is an important complement to that of Engelhardt and Szent-Györgyi and Polezhaev and Meerson.) Because abscesses often formed when vital tissue was implanted, Filatov tried sterilized tissue, and found that it was as effective in stimulating healing and regeneration. At this point he realized that tissue extracts would have the same effects, and he made and used extracts from a great variety of "stressed tissues," including leaves. He published results showing that sterile extracts could stimulate regeneration of the optic nerve, and of various other tissues. Many years after he died, people

at the Filatov Institute found that extracts of placentas were extremely beneficial to old people.

If there is a New Filatov who rejects the conclusions of Vladimir Filatov, and uses vital placental tissue, in a caricature of the experiments at the Filatov Institute, Paul Musarella certainly owes us an explanation, because his phrase, "the Russian scientist Filatov" is misleading. But I think Musarella is more likely just another person exploiting the gullible public, who are justifiably impatient with the failure of the medical establishment to work seriously on problems of aging and regeneration.

Although the *Townsend Letter for Doctors* deliberately avoids filtering out crazy ideas, I think a tiny editorial note at the end of such articles would be appropriate, commenting for example that no references were submitted, that the identity of "Pr. Filatov" wasn't explained, and possibly giving a little more information about the author.

Oral Absorption of Progesterone

JAMA, Volume 78, Number 3, 1986

SINCE many synthetic progestins are known to be luteolytic,[1] and while progesterone itself exerts a served in previous cycles, but in some women the effective dose caused the blood levels to rise somewhat above the levels usually considered normal for the luteal phase.

Postmenopausal women, who have much lower average levels of estrogen and who produce little progesterone, show much more clearly the effects of administered progesterone. Seven women who had gone through "natural" menopause at least two years previously, and whose serum progesterone was either below the sensitivity limit of the competitive protein-binding technique or in the typically low postmenopausal range of measurement by radioimmunoassay, were given oral doses of 50 mg or 100 mg of progesterone in tocopherol.

The earliest any blood was drawn after an oral dose of progesterone was 20 min; in this case, the progesterone had risen from 0.2 ng/mL before to 0.7 ng/mL after a dose of 100 mg.

When blood was drawn from 4 h to 8 h after an oral dose of 50 mg to 100 mg, the blood levels were between 6 ng/mL to 16 ng/mL. No attempt was made to assure that the progesterone was taken on an empty stomach; meals were eaten as usual while waiting for blood to be drawn. The progesterone was administered by the women's physicians, and the measurement was done by commercial medical laboratories.

In two cases in which blood was drawn 24 h after a single dose of 100 mg, the progesterone level was still in the normal luteal phase range.

Since the observations were made over a period of several years, with progesterone measurements made at several different laboratories by different techniques, the numbers are not strictly comparable. We recently got a clearer picture of the rate of absorption in a fasting person. A middle-aged man, with a fasting level of 0.2 ng/mL took 100 mg. At the first hour, the progesterone level was already 7 ng/mL; the concentration rose each hour to a peak at the sixth hour of 14 ng/mL, and the last measurement, at the seventh hour, was 0.2 ng/mL. On average, men's livers are quicker to remove substances from the blood, and the fact that no food was taken during the test very likely caused the rate of increase and the rate of decrease to be greater than in a nonfasting person.

In summary, when dissolved in tocopherol, progesterone is orally active. A single oral dose of 50 mg to 200 mg given to women with luteal phase insufficiency or to postmenopausal women brings their blood progesterone levels up to at least the normal luteal phase range and maintains it in that range for at least 12 h.

Oral Progesterone is Not Inactivated by Stomach Acids, Pancreatic Enzymes or Liver Detoxification

Townsend Letter for Doctors, February/March, 1995

STEPHEN Dentali, commenting on my remarks about oral progesterone, has indicated that "any pharmaceutical text" can be consulted to understand certain issues in pharmacology and pharmaceutics.

Textbooks are useful for introducing students to a new subject, and they are an interesting literary genre, allowing us to see how the individual author handles a certain area of knowledge. But anyone who has seriously studied a subject knows that textbooks aren't intended to resolve scientific questions. Different authors sometimes take different positions on the issues.

By reading many texts on a given subject, we can see that the people who write textbooks are usually far behind the decisive scientific work in most of the areas covered by their book. If they are researchers themselves, their particular area will usually be described in an up-to-date, though personally filtered, manner. Increasingly, publishers are influencing the content of textbooks, for the purpose of maximizing sales. (Richard Feynman's entertaining discussion of textbooks should be read by every teacher.)

It is important to critically examine original scientific publications, but textbooks are generally so far removed from the original work that it would be a waste of time to criticize their subjectivity and inaccuracy page by page. That isn't necessary, as long as people realize that they shouldn't be treated as anything but secondary (or tertiary) sources.

Many textbooks have said that since insulin is a protein, and since proteins are digested in the stomach, insulin is inactive when taken orally. Since oral insulin can cause lethal hypoglycemia in dogs (whose capacity to digest protein is very great), we can see the limitation of reasoning without evidence.

Progesterone happens to be very resistant to acid as well as to stomach enzymes, but ultimately the body is able to modify it into other substances, which are excreted.

Dentali invokes the "first pass" dogma of liver inactivation, but he neglects the whole point of what I said, namely, that chylomicrons are not consumed on the first pass though the liver. Progesterone equilibrates

from the chylomicrons into the other fractions of the blood, and a large part of it is carried in the red blood cells. Laboratories which measure the progesterone (or pregnenolone, or DHEA) contained in the serum after removing the chylomicrons and red blood cells are probably following some old textbook dogma, without realizing that they have discarded a major part of the hormone they would like to measure.

Dentali seems to have been offended by my reference to the "bizarre crystallization" that occurs in some progesterone products, and by my reference to FDA errors. I will respond to those points.

If the products that are unstable oily solutions bore labels warning users to heat and stir the mixture before use, they might be acceptable. But some of the products are in opaque bottles, and the physicians who prescribe them are not likely to suspect that the progesterone crystals have settled to the bottom. My patent is based on the fact that vitamin E stably holds progesterone in solution, so that it can be assimilated effectively by any route, transdermally, vaginally, or orally. Various companies have tried to take advantage of the awareness that my formula works, but I think some people have assumed that any product which contains "vitamin E" and progesterone will work in the way I have described. In the case of opaque transdermal (or rectal or vaginal) creams, the progesterone crystals in bad formulations are harder to see.

Spreading the cream in a thin film, they can be seen under a microscope. What is visible is not going to be able to go though the skin.

FDA officials have said that the only "approved" form of progesterone is the oily injectable form, which is described as progesterone dissolved in vegetable oil, with benzyl alcohol added as a bacteriostat. In "bacteriostatic water," benzyl alcohol may be present at 0.9 % to 1.9 %, and even at that concentration it is a dangerous neurotoxin and allergen. But the vegetable oil used as vehicle is a very poor solvent for progesterone, and it is not a hospitable environment for bacterial growth. (For example, it is a strong mutagen.) The so-called progesterone in vegetable oil needs the very high concentration of approximately 10 % benzyl alcohol to stay in solution on the shelf. When such a solution is injected, the toxic alcohol diffuses away into the body fluids, leaving the (cancer promoting) vegetable oil with progesterone, and the progesterone crystallizes out of solution. The benzyl alcohol is the actual solvent that permits the progesterone to stay in solution while the product is on the shelf. The massive amount of this neurotoxin in the

"approved" form of progesterone is reminiscent of the FDA's approval of a bronchodilator for asthma patients which contained metabisulfite as a preservative. When I told them that I thought that was an irrational product, since metabisulfite can kill people with asthma, and that the deadly "paradoxical" bronchoconstriction that was killing patients didn't seem paradoxical at all, they just didn't respond in any visible way. They similarly have not responded to the many complaints I have made about their "approved" form of progesterone. In another case, when I sent them evidence of what I believe is a gigantic and continuing drug fraud, they actually wrote me a letter saying they don't handle individual's complaints.

The FDA has done tremendous damage to women's health by claiming that natural progesterone has the terrible side effects of the synthetic progestins. This has never been a scientific issue: It is strictly a matter of the FDA's giving demonstrably false information to the public. Some of the widely used synthetic progestins have been powerfully estrogenic and teratogenic, while natural progesterone is neither.

Natural progesterone is known to be a safe and effective treatment for epilepsy, while all the recognized anti-seizure drugs are teratogenic, and it is largely the FDA's false attribution to progesterone of the side-effects of synthetic progestins that is responsible for the continued failure to make progesterone available to pregnant women with epilepsy.

Progesterone can be used as an anesthetic, but it is not correct to ascribe to it the properties of ether.

Progesterone has anti-inflammatory properties, but it is not correct to say that it must therefore have the properties of cortisol.

Progesterone has mineral-regulating properties, but it is wrong to classify it as a mineralocorticoid.

Long ago, Hans Selye pointed out some of the problems involved in classifying multiple action substances by one of their actions. But what the FDA has done goes far beyond any problem with sloppy scientific terminology. It has falsely claimed that the toxic properties of various synthetic drugs belong to natural progesterone. By their reasoning, if testosterone has a "progestational" effect on the uterus (as it does), then progesterone will produce whiskers and big muscles. If no one had tried to point out to them the egregiousness of their errors, I could believe that the FDA was innocently incompetent, but in fact they actively work to obscure the truth.

In this case, and in others that I have discussed elsewhere, I believe the FDA has taken irrational and antiscientific positions to protect the interests of the giant drug companies, to the great detriment of public health. They, and the companies they serve, should be held accountable for the death and disability resulting from their actions. Legally, I think patients, physicians, and pharmacists all have many bases on which to act against the abuse of power by people in the FDA. Illogical and arbitrary application of the law is simply illegal.

Origins of Progesterone Therapy

Townsend Letter for Doctors, November, 1992

By the beginning of the 20th century, the idea of extracting regulatory substances from animal tissues was coming into general acceptance in Western medicine. J. A. Lebreton, in Paris, was one of the first to argue for the therapeutic use of an extract of the corpus luteum. Around 1904, C. F. Burnam, of Baltimore, began using corpus luteum of the sow, administered orally, to treat the nervous symptoms associated with menopause or with the menstrual cycle, and also to treat functional amenorrhea, obesity, sterility, and habitual miscarriage.[1,2] By the 1920s, tablets of desiccated corpus luteum were generally available, and the daily dosage recommended (representing 6 g to 18 g of fresh tissue) contained a very substantial quantity of progesterone.

The chemical structure of pure crystalline progesterone was determined in 1934 (by Butenandt), and within two years many publications were reporting the beneficial effects of injections of the purified material. By 1935, animal research was confirming that the therapeutic work previously done with the crude extract had been on the right track. Although the early research showed that progesterone was very beneficial in threatened miscarriage, arthritis, infertility, cancer, and functional diseases of the nervous system, interest in this generic, public-domain material faded as the pharmaceutical industry found methods for converting it into proprietary synthetic glucocorticoids, estrogens, and progestins.

Animals are generally more sensitive to progesterone than humans are, and in animals no toxic level has been found, except that in the highest doses it is anesthetic. In humans, even this effect has never been reported in the medical literature, and it is clearly anti-toxic in nature. Besides preventing acute poisoning of many kinds, it also reduces the incidence of birth defects and cancer.

Progesterone, The Protective Substance of Youth

In 1971, I discovered that vitamin E and progesterone work together to sustain efficient production and use of biological energy.[3]

In the mid-1970s, I found that progesterone is the most powerful order-preserving substance (anti-chaotropic) on the cellular level, and that this explains its range of protective actions, from anti-toxic to anti-stress.[4,5]

Around 1980, I discovered that vitamin E, with its crucial effect on the mitochondrial respiratory enzymes, is a uniquely powerful, stable, and biologically compatible solvent for progesterone.[6]

Their intimate association at certain cellular sites requires mutual solubility. This property of mutual affinity extends to all biological areas, meaning that the solution of progesterone in vitamin E can be administered with exceptional efficiency by application to the skin or other membranes, or by ingestion, where normal digestive processes convert it into chylomicrons and distribute it to all tissues, allowing it to escape the tendency of the liver to convert it rapidly to an excretory form, as occurs when progesterone is administered in other forms.[3]

Because of its profound biological compatibility, the progesterone-vitamin E solution permits otherwise impossibly high doses to be given, increasing by as much as 2000 % progesterone's already dramatic effects in a wide range of major biological problems, including epilepsy, habitual miscarriages, auto-immune diseases, and cancer of the uterus, breast, and kidney.

Some Aspects of Basic Progesterone Research

By 1945, Hans Selye had demonstrated that progesterone in itself has the full spectrum of regulatory and anti-stress functions of the adrenal steroids.

A little later, Albert Szent-Györgyi showed that progesterone is able to regulate the heart, in a manner similar to digitalis. In the 1970s, I demonstrated that it acts similarly on vascular smooth muscle, regulating its tone and preventing venous pooling of blood, and maintaining normal filling of the heart, opposing shock. The immediate improvement in circulation can have dramatic effects, which include restoration of kidney function, elimination of fluid from the lungs, restoration of sensation in the feet, and healing of gangrenous toes.

It restores normal tone to other smooth muscles, including the gall bladder, urinary bladder, intestine, sphincters, and uterus.

Progesterone's ability to regulate thresholds of cellular excitation operates in nerves, as well as in smooth and cardiac muscle. It sensitizes nerves that regulate respiration, and has been used to treat infant apnea, sleep apnea in adults, and polycythemia vera in men.

In cases of specific progesterone deficiency in men, small doses can cure impotence. It has been used effectively to treat benign prostatic enlargement.

It normalizes fluid pressure, as in bursitis and glaucoma treatment.

It restores many of the functions of aged skin, and is the normal defense against calcium loss from bones.

It is one of the few essential requirements, besides nutrients, for nerve (brain) cell growth and survival. In young people of both sexes, the brain contains more progesterone than other organs do.

It is reasonable that progesterone, the dominant hormone in pregnancy, should have a full range of protective functions to protect the vulnerable organism during its intra-uterine life.

Practical Issues

A typical dose of progesterone/vitamin E, 20 mg/day for 10 consecutive days, costs about $1.00 per month, at the present retail price.

Pharmacists have the authority to compound drugs as they choose, just as physicians can prescribe the formulation they prefer.

Neither progesterone nor vitamin E has any toxicity when used orally.

Under federal law, a prescription is needed for a dosage form of a drug that is potentially harmful. In practice, the very dangerous injectable insulin is always sold without need for a prescription, presumably because its use is conceived as akin to nutrition, providing an essential natural substance to restore a natural function of the body. By analogy with insulin, the infinitely less dangerous progesterone should not require a prescription.

The logical way to make progesterone/vitamin E available to the public would be to license the patent to a chain of drugstores.

The availability of this effective and economical form of progesterone can hardly be kept secret, because people tell their friends, and patients eventually convince their physicians that it works.

An exclusive licensing agreement would be possible with 10 % royalties, based on the retail price, with a guaranteed sales volume, and with lower royalties for larger volumes.

Economic Questions

Because of its absorption by a natural digestive route which distributes it to all of the tissues, progesterone dissolved in vitamin E is almost 100 % absorbed when taken orally. Less than 1 % is absorbed from some types of suppositories, and less than 5 % absorption is typical. Taken orally as a micronized powder, pharmaceutical efficiency is only slightly better.

Most of the valid human research before 1981 used intramuscular injections of progesterone dissolved in vegetable oil and benzyl alcohol. Benzyl alcohol has a high affinity for water, and in contact with the tissue fluid, it leaves the mixture, causing progesterone crystals to form, since vegetable oil is a poor solvent for progesterone. Therapeutic blood levels of progesterone can be achieved by intramuscular injections, but at the cost of leaving toxic debris at the site of injection. Benzyl alcohol is a powerful neuro-toxin, but its harm is reduced by progesterone's anti-toxic action. The cost of the injectable progesterone, and of the injection itself, has been the main factor preventing wider acceptance of this form of progesterone in the United States.

Natural progesterone, and closely related steroids, occur in a wide variety of organisms. Up to the present, the cheapest source of the raw material has been the wild *Dioscorea* yam of tropical Mexico, but soybeans have also been used as the source of a steroid for production of progesterone. Since the soybean is a major source of vitamin E, the finished product can be made anywhere the bean is produced. Fenugreek, a quick-growing plant, contains the same substance as the Mexican yam, and can also be used as a source of vitamin E.

The chemistry for converting crude diosgenin into pregnenolone, and for converting pregnenolone into progesterone, is very simple, and can be done with little capital, at the site of production of the raw material. Interstate commerce needn't be involved, except for the economy of scale.

Osteoporosis and the Skin

Townsend Letter for Doctors, April, 1996

WHILE I was working on my dissertation, around 1970, the opposition between stress-injury and energetic resistance became increasingly apparent to me. Estrogen (like X-irradiation, aging, or trauma) called up the cortisone response, and other factors, especially progesterone and thyroid, allowed the organism to restore itself in ways that neutralized the cortisone response.

Therefore, when I saw that the estrogen-like processes became more and more dominant after middle-age, it was natural to think of progesterone and thyroid as the main factors that should be replaced. This is why in 1975 I described menopause as resembling Cushing's syndrome, which is caused by a toxic excess of cortisol.

Osteoporosis, hot flashes, insomnia, and mood disorders are caused by cortisol, and so I tried using progesterone and thyroid—the anti-cortisol factors—for those conditions. The results were so profound that I began to study the general implications for health, and to try to understand the mechanisms so that prevention might replace treatment.

Several people who had been abandoned as hopeless terminal cases—with "epileptic brain damage," inflammatory degeneration of hip and thigh bones, diabetic gangrene, senility—recovered their health within a few days, and went on with their lives in productive and pleasant ways.

I knew that intense and frequent epileptic seizures cause the exhaustion and death of brain cells. A 52 year-old woman had been having seizures for over 15 years. Her neurologist gave her a mental exam every year, and considered her to be hopelessly demented. After using progesterone for a few days, she functioned normally. After about a year, she returned to graduate school at the University of Oregon, and got a master's degree with straight A's.

A 79 year-old woman had had artificial hip joints implanted when she was in her fifties, but her bones had weakened to the point that no further surgical repair was possible. She settled her affairs, and didn't expect to get out of bed again. After using progesterone topically and orally, after two weeks she was able to get out of bed and return to her normal activities. At the age of 85, she went camping on the beach in Mexico, and travelled to Scotland.

An 82-year old man was agitated and confused, and was apparently suffering from senile dementia. After being given progesterone and pregnenolone for a few days, his mind became clear, and he returned to work on scientific projects he had begun decades earlier. A squamous cell cancer on his lip regressed, and never bothered him again.

A 60 year-old woman had "osteoporosis" (shrinking) of the jaw bone that was causing her teeth to loosen. After applying progesterone solution to her gums daily for a few months, her teeth became firm.

When bones had almost disappeared from X-rays, yet became firm and functional within a few weeks, it was obvious that regeneration had taken place. But when brains went in a very short time, from imbecility or idiocy to intellectual productivity, I could only guess what might be happening to the cells. But I got a useful perspective on the mechanism of progesterone's action by seeing some recoveries that were even faster than those I have mentioned.

In animal experiments, I knew that estrogen causes cells to take up water within a few minutes after it reaches the tissue, and that this is at least partly the result of its interfering with the availability of oxygen. Within 40 minutes of administering a large dose of estrogen, the lungs become extremely inefficient at oxygenating the blood. This involves a sudden thickening of the alveolar membranes and the walls of capillaries, simply by taking up water. So, when I saw bulging veins disappear a few minutes after women took progesterone, along with a sudden lifting of extreme depression, I guessed that their circulation had become more efficient, and that better oxygenation had changed their mood.

Then, I repeatedly saw physical changes in other people that were visible within an hour, and that involved a sudden movement of water out of edematous tissues. In many people with damaged joint cartilage (confirmed by various types of examination, including arthroscopy), the joints became mobile in an hour, and by the next day, the defect no longer existed. A man who was purple from emphysema changed color within a few hours, and within a few days was going to work. The bulging eyes of exophthalmic Graves' disease receded into their sockets noticeably within an hour, and were normal the next day. Simply increasing the circulation couldn't have done those things. Opposing estrogen's edema-promoting action was involved, but I couldn't imagine any mechanism that could explain such rapid movement of water from the swollen tissue into the bloodstream.

One of estrogen's effects is to lower the amount of albumin in the blood. Estrogen causes the liver to synthesize less albumin, partly by causing the messenger RNA to be destabilized and degraded. (Iron can have some similar effects on liver RNA.) When there isn't enough albumin in the blood, water moves from the blood into the tissues, causing edema. (Premenstrually, edema might seem to be just a nuisance, but it can eventually become a serious problem, with aging or pregnancy, for example.) Albumin binds oily substances, and its conformation seems to be opened when it binds them. Progesterone is known to adsorb strongly to proteins—it has been called a "cardinal adsorbant," meaning that it can bind in ways that cause the protein's adsorptive capacity to change. I believe that progesterone and pregnenolone oppose estrogen in many ways, but the amazing speed with which they can cause major structural changes in the soft tissues convinces me that one of their first sites of action is the albumin molecule, causing its conformation to open in such a way that it is able to more strongly bind water molecules. This physical change in albumin would change the blood's osmotic/oncotic pressure, causing water to flow into capillaries. As the edema is reduced, oxygenation is more efficient, because the pathway for oxygen diffusion becomes shorter.

Albumin has been described as a first line of defense against toxins, since it binds them until the liver is able to degrade them chemically. Progesterone, pregnenolone, and cholesterol are known to increase the organism's resistance to a great variety of toxins. (Selye coined the name "catatoxic steroids" to describe steroids of this type.) If these steroids bind to albumin in a way that opens the protein to increase its binding capacity, that single process could explain the "catatoxic" effect, as well as the anti-edema effect.

When the blood is unable to retain its normal amount of water because of insufficient albumin/sodium, the blood volume is reduced as the tissues become water-logged. This causes the hematocrit (the proportion of cells in a volume of blood) to rise, and this increased packing of red blood cells causes the blood to become more viscous. Knisely studied this phenomenon in a great variety of sicknesses. Increased viscosity and slower flow decrease the blood's ability to deliver oxygen and nutrients to the tissues, including the blood vessel walls, modifying their tone. Slower flow, even without any changes in the fibrin/fibrinogen system itself, increases the formation of clots.

This description of progesterone's immediate action is intended to take some of the mystery out of its dramatic effects, but it isn't intended to argue against any of its actions within cells. It serves to give a general picture of how progesterone can systematically reduce stress and its harmful consequences, just by making blood circulation more efficient.

At first I most often used progesterone dissolved in olive oil to stop the stress-induced processes of deterioration, with a high protein diet to support the processes of repair. Now, I have added a variety of other techniques.

There always seems to be a rough balance between tissue regeneration and tissue degeneration, with growth and repair occurring when the equilibrium shifts in one direction, and with atrophy or degeneration occurring when the balance shifts in the other direction. If we can understand the mechanisms of atrophy, and how to retard or to block tissue destruction, then we can restore the balance to a degree which might allow regeneration to occur, even if we don't clearly understand the mechanisms of growth.

Skin and bones are such different types of tissue that it will be useful to start with them, because if we can see similar processes of degeneration or regeneration in them, then the chances are good that the same processes will occur in other tissues too. Bone is a relatively stable tissue, while skin is a tissue whose cells divide rapidly.

It is common medical knowledge that cortisone and related glucocorticoid-type hormones cause skin to atrophy, becoming thinner. Using topical applications of a synthetic derivative of cortisone, C. M. Papa and A. M. Kligman showed that the atrophy extended to the pigment cells, reducing their size and eliminating most of their dendritic branches. They also found that estrogen caused the skin to become thinner. The other steroids they tested, progesterone, testosterone, and pregnenolone, acted in the opposite direction, making aged and atrophied skin thicker and more regular. They also made the pigment cells larger, and increased their branching.[1]

Since these hormones were already known to have protective actions against cortisone and estrogen, these results were not too surprising, though they did directly contradict the claims of people who made estrogen-containing cosmetics.

Since progesterone and pregnenolone do not cause healthy, young skin to thicken, their effect in damaged skin is probably partly to replace

the deficiency of that type of steroid which occurs with aging, and to offset the damaging effects of the catabolic hormones, whose influence does not decrease with age.[2]

Many years ago it was found that in old age a woman's estrogens were increased relative to the 17-keto steroids adrenal androgens. Later, it was found that the conversion of androgen to estrogen increases with age in both men and women, and that this occurs largely in fat cells. Several years ago, P. K. Siiteri found that low thyroid modified the enzymes of fat cells in a way that would tend to increase the conversion of androgen to estrogen. More recently, it was found that adding progesterone to the enzymes had the opposite effect of aging and hypothyroidism, protecting the androgen from conversion to estrogen. These researchers (C. J. Newton and colleagues, of London) concluded that the decreased output of progesterone after the menopause might account for the increased production of estrogen.[3] Since progesterone declines in aging men, too, this could account for the same process in men.[2]

Vitamin A's effect on the skin opposes that of estrogen. There are several mechanisms that could account for this.[4] Vitamin A is used in the formation of steroids, and since the skin is a major site of steroid metabolism, vitamin A might help to maintain the level of the anti-catabolic steroids. A deficiency of vitamin A causes excessive release of the lysosomal enzymes, acid hydrolases, resulting in tissue catabolism.[5] Also, vitamin A is necessary for the proper differentiation of cells in skin and other membranes. A deficiency tends to cause an increased rate of cell division, with the production of abnormal cells, and a substitution of keratinized cells for other types. Estrogen also promotes keratinization and speeds cell division. A deficiency of vitamin A can cause leukoplakia in the mouth and on the cervix of the uterus; although this is considered "pre-cancerous," I have found it to be very easily reversible, as I have discussed elsewhere.[6] I suspect that the intracellular fiber, keratin, is produced when a cell can't afford to do anything more complex. Adequate vitamin A speeds protein synthesis,[7] and allows it to be used more efficiently.

Prolactin (which is promoted by estrogen, and inhibited by progesterone) increases with stress and with age. It probably affects every tissue, but it seems to have its greatest effects on the secretory membranes. It is known to have strong effects on the kidney, gut and skin (sweat and oil glands, hair follicles, and feathers in birds), and on the gills of fish.

Its involvement with milk production suggests that it might mobilize calcium from bones, and in fact it does contribute to osteoporosis. This was foreseen by G. Bourne, in his book on the metabolism of hard tissues, when he suggested that estrogen, acting through the pituitary, might be expected to promote osteoporosis.

Since reading Bourne's book, I have doubted that it was rational to use estrogen to prevent osteoporosis, especially when it is known to be carcinogenic and when the ratio of estrogen to androgens and progesterone increases after menopause. Now that several publications have appeared clearly showing that estrogen increases prolactin, that prolactin increases with aging, and that prolactin contributes to osteoporosis, the postmenopausal use of estrogen is worse than dubious. But this was exactly when the pharmaceutical companies needed help in continuing to sell their profitable estrogens, and this was exactly the time when the FDA came out with its official approval of estrogen for preventing osteoporosis.[8]

Some doctors combine estrogen with testosterone, and this is much safer and more likely to keep the bones healthy. But since testosterone, like estrogen and cortisone, causes the thymus gland to atrophy, it is not a very good idea for chronic use, even if it doesn't cause masculinization. The other anti-estrogens, which are present at high levels in young women, include progesterone and DHEA. I have seen several publications which I think would justify the use of physiological amounts of DHEA to prevent or to treat osteoporosis,[9,10] and a few which support the use of progesterone.[11,12] My own observations on their use in osteoporosis have been presented many times at alternative medical conferences since the 1970s, but the main-line medical journals and conferences have declined to accept my reports, even when they advertise that all papers submitted will be presented in some form; many physicians believe that they are being presented with a fair sampling of the work being done in endocrinology, when in fact they are being given intensive advertising sessions.

Since it is known that cortisol causes bone loss, and it is widely accepted that progesterone has an "anti-glucocorticoid" action, it is reasonable to think that progesterone should protect against bone loss, and that it is a progesterone deficiency after menopause which is a major factor in the development of osteoporosis. In the first edition of *Nutrition for Women* (1975) I pointed this out, in comparing menopause to Cushing's

disease. Nencioni and Polvani more recently made observations which support this mechanism, in which progesterone "exerts a protective effect," by blocking the corticosteroid receptors. They observed "that the process of rapid bone resorption starts before the onset of amenorrhea and the abrupt fall in the estrogen levels and coincides with decline in progesterone secretion."

By improving blood circulation and oxygenation of the tissues, progesterone and pregnenolone will decrease the need for the body to produce cortisol. Pregnenolone acts in the brain to decrease the basal secretion of ACTH. This protective effect is more basic than that achieved by blocking the cortisol receptors.

The early tests of the toxicity of vitamin A used cartilage in tissue culture. The same enzymes which are released by a deficiency of vitamin A are released by a large excess, causing dissolution of the cartilage. Other studies showed that a vitamin A deficiency caused similar changes in both bone and cartilage. Although much vitamin A is consumed in the production of progesterone, these studies show a direct effect of the vitamin on tissue stability. Although I believe that a vitamin A supplement will offer considerable protection against osteoporosis (and also against aging of the skin), it is important to remember that excessive vitamin A inhibits the thyroid, and that there is less risk of toxicity when vitamin E is supplemented too. I think many of the headaches currently associated with vitamin A use are the result of a preservative in the capsules (probably a sulfite), since some people who react to the vitamin in capsule form don't react when they use a specially ordered bulk form prepared without preservatives.

Things which damage skin and bones also damage other tissues, and things which protect them also protect other tissues. The protective factors include hormones (thyroid, DHEA, progesterone, and pregnenolone), vitamins A and E, and minerals—including magnesium, calcium, and sodium. Sodium spares magnesium, and helps to make albumin function in regulating blood and tissue water content. Under some conditions, sodium can act as an antioxidant. Since the unsaturated oils (and their prostaglandin derivatives) decrease respiration, cause stress to be more harmful, and have some specific effects that promote aging of skin, bones, and other tissues, the use of coconut oil is especially important. I think its use is one of the factors that prevents osteoporosis in tropical countries.

Progesterone Can Be Taken Orally

Townsend Letter for Doctors, November, 1994

YOUR June review of Betty Kamen's book on hormone replacement in menopause, osteoporosis, and PMS made some good points, but it repeats a serious error, that progesterone "cannot be taken orally."

I believe that idea was a simple fabrication of someone in the drug industry in the 1940s to promote their own new synthetic progestin, because I could never find the source for the idea, which simply began appearing in the literature without supporting data, when new products needed promotion.

Human milk from healthy women contains significant amounts of progesterone, which makes milk an important part of the infant's endocrine system. Associated with fat droplets, progesterone enters the blood by the chylomicron pathway, permitting it to avoid inactivation or excretion.

When taken in the powdered or micropulverized form (even if the powder is packed in oil) progesterone doesn't enter the blood as chylomicrons, and so is quickly processed into a water-soluble metabolite, which is excreted. This metabolite cross-reacts with active progesterone in the usual analysis of blood levels, and creates some medical confusion, since symptoms and measurements don't relate in the usual ways.

Betty Kamen cites my book, *Nutrition for Women*, as a source for the idea about oral progesterone. I believe she might not have read my material itself, since my comparisons in that book had to do with the superiority of skin-absorption over injected progesterone. In many other publications, including *Progesterone in Orthomolecular Medicine* (all my books are available directly from me), and several articles in the *Townsend Letter*, I have described the efficacy of oral progesterone dissolved in vitamin E.

I have the patent on that form, and some manufacturers have unscrupulously implied that they are using my formula. I have tested several such preparations, in preparing my patent infringement case. Recently I have examined some of the products of a Portland company (a company which has led many people to think I am involved in their business). What I found was that the progesterone had rapidly gone out of solution, forming bizarre hair-like crystals, which gave the solution

a slightly stringy texture. Natural progesterone in natural vitamin E remains stable in solution, and I believe the only explanation for the bizarre crystallization that I and others have observed would be the use of synthetic polymer-substances in the solution. In that form, it doesn't infringe my patent, but it would seem to be mislabeled and misrepresented.

The FDA has erroneously classified progesterone with synthetic progestins, and hasn't made any attempt to help the public separate promotional fictions from physiological facts. In fact, they have themselves created additional fictions about progesterone, ascribing properties of the synthetic progestins to progesterone itself, resulting in tremendous injury to the public health. (If that agency strictly followed the rules of administrative law, it might not be perceived as the servant of the industry which it is supposed to regulate.) The ineffectiveness of oral progesterone is one of the fictions that needs to be corrected, and the popular and alternative medical press is where that correction can be achieved. Betty Kamen's book is better than most of the books on osteoporosis and menopause, but it looks a little too much like a promotional effort in support of Dr. Lee's cream, and I am sorry that one of my books is mentioned as seeming to support the fiction that the skin cream is better than the oral oil form.

If she ever rewrites the book, I hope she will consider the evidence that thyroid hormone plays a major role in rebuilding bones, and that unsaturated oils (via prostaglandins and a variety of other hormonal derangements) and estrogen (via promotion of prolactin) have a role in causing osteoporosis. Oral progesterone dissolved in vitamin E is a powerful protectant of every system and tissue, including the bones, but it is important to understand its wonderful effects in the contexts of physiology and ecology. I think the properties of natural progesterone provides us with a scientific paradigm, similar to the concept of "adaptogens" in medicine, but even more basic, involving physical self-ordering processes. Increasingly, our health will depend on understanding this paradigm of life's resistance to harm.

Progesterone Content Corrected

Townsend Letter for Doctors, June, 2000

BURTON Goldberg's article on fibroids[1] indicates that Aeron LifeCycles lab reported the progesterone content of Progest-E Complex as being between 1000 mg to 1500 mg per ounce. I was told a couple of years ago that this figure was mistakenly introduced into John Lee's book by the book's editors. That product, made under my patent, has never deviated from its 10 % progesterone content, so it contains 2850 mg of progesterone per ounce, and I don't know of any test that has found otherwise. As I understand it, Dr. Lee's book was later corrected.

Progesterone: Essential to Your Well-Being

Tides of Life, January, 2000

THE hormone progesterone participates in practically every physiological process, in both men and women. Its tremendous increase during pregnancy serves to stabilize the organisms, both mother and child, during that crucial time. At levels reached just before delivery, progesterone produces anesthesia and contributes to tissue elasticity. The fetus requires large amounts of glucose, and progesterone makes it possible to be provided in abundance for ideal brain growth, by promoting the mother's ability to use fat for her own energy. It is this efficient use of fat which gives women greater long-range endurance than men. When progesterone is deficient, there tends to be hypoglycemia, often combined with obesity.

The stabilizing action of progesterone is especially visible in muscle tissue, such as the uterus, blood vessel walls, the heart, the intestines and the bladder. Less visibly, progesterone stabilizes and normalizes nervous, secretory and growth processes. Biochemically, it provides the material out of which all the other steroid hormones (such as cortisone, testosterone, estrogen and salt-regulating aldosterone) can be made as needed. Progesterone's simple molecular structure allows it to balance either an excess or deficiency of those other hormones, even when there is a defect in their synthesis.

Many factors, including poor nutrition, climate, emotional or physical stress (even excessive running) and toxins, can cause a progesterone deficiency. Use of estrogens, birth control pills and even IUDs can also bring about a deficiency. Animal studies and clinical experience suggests that the prenatal hormonal environment (a mother's excess of estrogen during pregnancy) can incline a person toward a deficiency of progesterone relative to estrogen.

Recent studies show that progesterone prevents stress-induced coronary blood vessel spasms in aged hearts-probably explaining women's relative freedom from heart attacks, so long as they retain functioning ovaries. Other studies suggest that progesterone has a role in regeneration of damaged brain cells and prolonged growth of the brain. Delayed aging and longer life span have been very clearly related to extra progesterone. Many types of tumors have been prevented and helped

with progesterone. Excessive blood cloning caused by excess estrogen alleviated by progesterone. Pregnancy toxemia and tendency to miscarry or to deliver prematurely are often corrected by progesterone. When epilepsy occurs premenstrually, or first appears around puberty, it is often stopped by progesterone therapy. The hormone has been used successfully in suicidal depression, Reynaud phenomenon, Meniere's disease, agoraphobia (especially when associated with porphyria, an abnormality of liver metabolism), Bright's disease (a kidney disorder) and, used as a lotion, in a variety of genital skin problems in children, adults and postmenopausal women. Hot flashes and other menopause problems respond to progesterone therapy.

Since progesterone normalizes the immune system (it causes thymus regeneration, for example) it is very effective in autoimmune diseases (which result from adverse reactions to one 5 own tissues) and in those degenerative disease which have an autoimmune component.

In several ways both progesterone and thyroid hormone can be considered primary regulatory hormones. Both of them regulate metabolism directly at the energetic and synthetic levels: both have a normalizing, anti-stress action on the pituitary gland; and each has a promoting action on the other. Both are blocked (and consumed) by stress and promoted by light and good nutrition. Both are nutrients in cultures that eat the whole animal, including ovaries and thyroid, butter, cream and milk contain small amounts of progesterone and shellfish seems to be a good source.

Disregarding most of the information promoted by pharmaceutical companies and the medical texts and journals which for 30 years have reflected the opinion of those companies (especially regarding the patented synthetic estrogens and glucocorticoids), we can trace a line of research and ideas on the sex hormones, from pioneers such as Loeb, Korenchevsky, and Selye, through a generation that continued to demonstrate the toxicity of estrogen, and the value of progesterone including people like Lipschutz, Dalton and Soderwall.

In my dissertation research under Soderwall, I had the opportunity to collect and assimilate data indicating an increased estrogen effect in aging animals and recently, with newer techniques, I have seen similar changes in many menopause women. My research showed that the probable mechanism by which estrogen excess causes infertility is through limiting the availability of oxygen. I showed that anti-estrogenic

substances, such as progesterone or vitamin B, increased the oxygen content of the uterus. This anti-oxygen effect of estrogen suggests a convergence of reproductive aging research with Warburg's theory that damaged respiration is the primary defect in cancer and also with Selye's observation that estrogen's effect resembles the first shock phase of stress reaction.

Early research had also shown that estrogen diminishes liver glycogen storage while progesterone increases both blood sugar and liver glycogen. It is well known that hypoxia (oxygen deficiency) damages the fetal brain, but probably less well known that hypoglycemia—either chronic or acute—can cause brain damage and retardation. Oxygen deficiency, by lower metabolic efficiency, will cause hypoglycemia. Estrogen causes hypoxia at every imaginable site, from lung, through vascular fibrin (clot material lining blood vessels and red cells) and extracellular collagen (a glue-like part of connective tissue) and edema, to intracellular metabolism. Estrogen is also a promoter of insulin release and action, lowering blood sugar and promoting fat synthesis. Estrogen and another common anti-oxygen material, excessive unsaturated fats (vegetable or fish oils) have both been demonstrated to cause the birth of small-brained, retarded animals. Recent studies imply that about half the children identified as hyperactive have experienced prenatal stress. The most urgent need for progesterone therapy, I think, is preventing a continuing epidemic of brain damage. Beyond that, many studies have found that the use of natural progesterone increases a child's IQ, typically by around 35 points and produces personalities that are more "independent, individualistic, self-assured, self-sufficient and sensitive."[1]

Progesterone vs. Hypoglycemia

Protection against hypoglycemia is probably the main mechanism. Diabetic mothers often have precocious children, if they aren't damaged by drugs and irrational diets. 10 g to 15 g per pregnancy, at increasing dosage, seems to be the optimal amount, when there is some sign of excessive estrogen or unexpected toxemia. The American Medical Association Department of Drugs, which warns against certain sex hormones being used during pregnancy, has specifically excluded progesterone from those others which are "now contraindicated in early pregnancy."[2]

Hypoglycemia (which can result from any respiratory defect) can produce malfunction of any tissue, but brain dysfunction and immune dysfunction are very common effects. Adamkiewics has shown that allergic reactions to a given substance will decrease from 100 % to 0 %, when the blood glucose increases from, for example, 50 mg to 150 mg or more. Soviet research shows a similar involvement of blood sugar level in various "psychosomatic" ailments. Progesterone (and thyroid) will help in most allergic diseases, including the autoimmune and "collagen diseases," because it helps to maintain blood sugar (promoting respiration and improving use of fat-sparing glucose) and also because it stabilizes lysosomes (enzyme packets in cells, which are involved in inflammation processes).

The group of enzymes known as superoxide dismutase (SOD) are probably involved in the protective effects of progesterone, since one of my assays to determine the action of estrogen turns out to be an inverse indicator of SOD-that is, progesterone would seem to turn on this protective enzyme.

Although progesterone and cortisone both raise blood sugar and stabilize lysosomes, their effect on the brain is very different. In large doses, progesterone is sedative and anesthetic, while cortisone is stimulating and causes changes in the brain, which resemble aging. An excess of cortisone also tends to elevate estrogen, which was found (in animal experiments) to interfere with memory. High estrogen traits can be acquired by environmental stress and can be passed on to offspring, as discovered by L.C. Strong in his mice, and as confirmed recently in rats that were stressed during pregnancy.

It has been observed that the ratio of brain weight to body weight corresponds directly to longevity. The brain has a nourishing, trophic influence on other tissues. A stable, efficient brain is an anti-stress agent. The hormones of stress age various tissues, including connective tissue. Good nutrition, including the anti-stress substances found in certain foods, will simultaneously optimize intelligence and increase the healthy life span. Congenital defects are increased by stress and poor nutrition during pregnancy and, conversely, reduced by good nutrition hormone supplementation and stress reduction.

An excessive estrogen/progesterone ratio is more generally involved than either a simple excess of estrogen or a deficiency of progesterone, but even this ratio is conditioned by other factors, including age, diet,

other steroids, thyroid and other hormones. The relative estrogen excess seems to act by producing tissue hypoxia. Symptoms in cycling women are most common around ovulation and in the premenstrual week, when the estrogen/progesterone ratio is normally highest. The early 20's, late 30's and menopause are the periods when the ratio is most often disturbed. These are also the ages when thyroid disorders are commonest in women.

I have observed the use of progesterone transdermally (applied to the skin) in about 400 women suffering from the full range of perimenstrual symptoms, including migraine, acne, depression, mastalgia (breast pain), edema (water retention and swelling), and lethargy. I found that nearly all the women who apply the lotion themselves, are able to find the appropriate dosage for controlling their symptoms. Occasionally, thyroid therapy, weight reduction: or change in some aspect of lifestyle is necessary for complete relief from symptoms. When some women said the progesterone had no effect, it turned out that they were applying it as sparingly as they would a rare perfume-just touching it to their wrists.

Anesthesia (or drunkenness) from a very large overdose is the only negative side effective reported in the literature. Experimenting with very large doses of natural progesterone on myself, for migraine, I found that there is a temporary antagonism to testosterone, causing small symptoms, including a slight sense of gregariousness, an urge to socialize. However, synthetic progestins do have harmful side effects including breast tumors. Unfortunately, most physicians do not yet know the difference between natural progesterone and synthetic progestins.

At our health resort/clinic, we're finding that most women respond dramatically to progesterone support, but don't remain chronically dependent on it. During their stay, clients are provided specialized, indulgent care, along with progesterone and other therapies. We consider it essential, as well, to teach them the principles of maintaining optimum health through good nutrition. Results are impressive and usually permanent.

Repairing Immunodeficiencies

Townsend Letter for Doctors, November, 1989

Last summer's death of most of Europe's seals from viral diseases suggests the possibility that their immune systems were weakened. The coincidental publication last spring of a study of the relatively remote Arctic seals of Spitzbergen,[1] which found surprisingly high levels of dioxins and other toxins in the animals, suggests that the aquatic carnivores closer to the sources of pollution might simply have been the first large group of animals to reach an intolerable level of chemical immunosuppression. The people who eat the same fish that the seals eat, and breathe the same air, might also be experiencing some degree of increased susceptibility to infections.

For several decades, the death rate from some kinds of opportunistic infection has been increasing,[2] and as bacterial infections came under control in the 1960's they tended to be replaced by less common infections such as *Pneumocystis carinii*.[3]

Acquired (or secondary) immune deficiency has been a familiar phrase in immunology for at least a generation, and the recognition of the condition itself, under different terms, has been part of medical knowledge for many generations. Before 1981, typical textbooks listed cancer, chemotherapy, ionizing radiation, malnutrition, aging, parasites, fungal infections, and viral infections among the known causes of acquired immune deficiency.[4]

After 1981, the term "acquired immune deficiency syndrome" was appropriated by the molecular virologists, who were familiar with the ability of viruses to cause immunosuppression, and who, with impressive speed, determined that the "new" syndrome was caused by a certain new virus, the human immunodeficiency virus (HIV) or the human T-cell lymphotropic virus type III (HTLV-III).

Peter Duesberg was one of the few molecular virologists who doubted that a virus of that sort, all by itself, could cause disease.[5] An important implication of the identification of the HIV as the cause of AIDS has been—for the molecular virologists who ignore Duesberg—that a specific vaccine or genotoxic chemical should be able to destroy the specific pathogen. Very little attention has been given to the question of whether a person's good health can be maintained despite the presence

of the "viral gene." And the lingering effects of the "central dogma" of molecular genetics still discourage serious investigation of the question of whether such genes can be cleared from the genome under certain conditions without destruction of the cell.

Since human exposure to known immunosuppressants has been increasing during the years that the incidence of opportunistic infections has been growing, a real investigation of the cause or causes of AIDS will involve doing some scientific epidemiology, to learn whether some factor other than the HIV has a crucial role.

Some of the factors that I have given attention to, in working with "ordinary" (i.e., complex, traditional) immunodeficiency—*viz.*, a deficiency of the anti-glucocorticoid hormones, a dietary excess of iron and unsaturated fats,[6] a nutritional deficiency of vitamin A, folic acid, copper, and protein, an exposure to pediculocides and other chlorinated hydrocarbons including dioxins, etc.—should probably be included in such an epidemiological study. Even if such factors turn out not to be crucial in AIDS-HIV, my informal studies and observations since 1973 indicate that examining and correcting as many of them as possible can, inexpensively and safely, promote recovery from many chronic infections and other diseases associated with some degree of acquired immunodeficiency. Whatever the cause of AIDS associated with viral infection may be, it is likely that an appropriately designed supportive treatment will at least slow the progress of the disease.

In spite of a few virologists who still claim that there is no such thing as an immune stimulant, hundreds of immune-promoting substances have been studied and described, and a few of them (e.g., levamisole, inosiplex) are well-known. Although more meaningful tests are now available, skin tests have been used for several decades to demonstrate that immune stimulants or improved nutrition[7] can reliably shift the immune system from anergy to reactivity. Anything that intensifies metabolism tends to be an immune stimulant, other things being equal. A subnormal temperature is a common feature of chronic infection and early cancer, until a late stage of intense catabolism with fever.

Since most of the immune stimulants are harmless, compared to the genotoxins, the reluctance to test them is ideological, rather than scientific. My *Stedman's Medical Dictionary* (23rd edition) illustrates the psycho-linguistic environment: "immunodeficiency" and "immunodepressant" and "immunosuppressant" are defined in a way that any

native English speaker would understand. However, "immunological enhancement" (p. 464) is explained as involving the suppression of cell-mediated immunity (to prevent rejection of a tissue allograft). A major part of the history of medicine seems to have dropped out of medical English.

In one line of thinking a variety of malfunctions of immunity can be created by a single factor, such as energy deficiency, acting within the organism's special history or constitutional individuality. Allergies, auto-immune disorders, and chronic infections or skin-test anergy, can be seen as aspects or phases of a generally impaired reactivity of the organism, shaped by many trophic influences of nerves, hormones, nutrition, and by toxins, temperature, radiation, etc.[8] Accordingly, I have recommended the use of techniques of immunity-promotion (or normalization) for allergies, auto-immune disorders, and chronic infections or immune deficiencies, taking into account the person's history of environmental insults, nutritional deficiency, family traits, and present hormonal, nervous, and metabolic status as far as possible.

Beginning in 1973, a clinic in Eugene, Oregon (a city which is notorious for allergies, because of the surrounding grass-seed farms which produce pollen in the spring, and smoke from field-burning in the summer and fall) had very good results with their allergy patients when they gave them supplements of vitamin A, pantothenic acid, and vitamin C. Later, thyroid extract or triiodothyronine and magnesium were added to the other supplements for patients who had problems more serious than ordinary allergies. We found that many people with acne, bladder or kidney infections, periodontitis and sinusitis seemed to be deficient in both thyroid and vitamin A even when they were taking supplements of those materials. At higher doses of both, many of those people quickly got over their infections. Many people with colitis, myositis, bursitis and arthritis had sudden relief from their symptoms on this, or a similar program. We have assumed that some toxin might be interfering with the biological effects of thyroid and vitamin A.

If thyroid and vitamin A can't be used efficiently to form steroids, a steroid imbalance is likely. Unopposed cortisol is immunosuppressive in several ways, including thymic hypoplasia,[9,10] depression of the histaminolytic activity and mono-oxygenase activity of the liver, contributing to chronic allergies,[11] and it can induce the expression of some types of retrovirus.[12]

Although one of the important functions of vitamin A is its involvement in the formation of the steroids pregnenolone and progesterone (both of which moderate the effects of cortisol), it also has some hormone-like actions directly on the cells of the immune system, and it stimulates production of interleukin-2 and both inhibits generation of specific suppressor cells and limits the intensity of activation of suppressor cells.[13] The possibility of vitamin A toxicity is reduced by using the thyroid hormones and vitamin E.

Pregnenolone and progesterone have a vitamin A-sparing effect, besides their direct protective action for the thymus, and they also have the very general protective action which Selye called "catatoxic." Both of these hormones have been effectively used to treat various auto-immune ailments. They tend to raise the body temperature and metabolic rate, yet they are anti-catabolic.

Vitamin A, thyroid, progesterone, and the related steroid, dehydroepiandrosterone, all oppose estrogen, which has several immunosuppressive effects, including a cortisol-like thymic atrophy, hypoactivity of T cells, and reduced production of gamma-interferon and interleukin-2, reduced natural killer cell activity, and it probably has a role in the development of some auto-immune diseases.[14] Subnormal body temperature promotes estrogen secretion.

AIDS, which has been called "slim disease" in Africa, often ends with extreme wasting. Many physicians are horrified at the thought of treating immunodeficiency with thyroid, because they associate hyperthyroidism with weight loss. Two young women, who were diagnosed as having "allergies" and supposedly auto-immune pituitary hormone deficiency, and who each weighed around 70 pounds and was considered to be "terminal" (though they both ate normal amounts of food), recovered quickly with a thyroid supplement and a diet emphasizing eggs and fruit. About 80 years ago, when surgery was first being done to remove goiters, the whole gland was removed, no supplementary thyroid hormone was given, and the patients often died of a wasting syndrome, which was named "cachexia strumipriva." Thyroid function is essential to all cell processes, including protein assimilation and synthesis, formation of growth hormone, etc. Without thyroid hormone to sustain respiration, inefficient glycolysis wastes energy; unoxidized lactate provokes catabolism of liver protein. Hypoglycemia stimulates secretion of glucocorticoids, which maintain blood sugar at the expense of rapid catabolism of protein. It

is characteristic of people dying with AIDS to have no thymic tissue, as well as having other signs of extreme stress. It seems clear that a safe anti-stress, anti-cachexia, thymus-protecting program would have prolonged their life.

Triiodothyronine is often the essential factor in reversing a cachectic state. Although optimal thyroid function can increase the metabolic rate, it is not catabolic because it maximizes bioenergetic efficiency.

Adamkiewicz demonstrated the importance of blood glucose in anaphylaxis and allergy.[15] In a vicious circle, histamine tends to exacerbate hypoglycemia (e.g., by its acetylcholine-like actions) and it is directly immunosuppressive in many ways. It inhibits lymphocyte proliferation in response to stimulation, it inhibits antibody formation and lymphocytotoxicity, it suppresses cutaneous delayed hypersensitivity and release of lymphokines, and it suppresses both the generation of T-helper cells and their effector functions.[16–19] Besides the ordinary antihistamines and receptor blockers, the release of histamine can be inhibited by many other substances which are immunoprotective, such as epsilon-aminocaproic acid, and by the saturated fatty acids, from pentanoic to dodecanoic.[20] These fatty acids are known to be assimilated as quickly as glucose, and so it seems likely that part of their antihistamine effect is similar to the glucose effect demonstrated by Adamkiewicz, and that both effects could be largely the result of increased availability of metabolic energy. Since tumors often contain very large quantities of mast cells, immune therapy for tumors should take histamine into account. Since 1970 I have experimented with some unconventional anti-inflammatory substances, including some of the local anesthetics, which seem to have a safe and effective antihistamine action. I think some of the anti-cholinergics which have "anti-viral" activity (e.g., amantadine) are analogous in their mechanisms of activity.

Around 1960, ammonia was found to have an "anti-viral" effect, apparently by altering the host cell's structure or function, rather than by a direct virucidal action.[21] Following that discovery, many amines were found to have some anti-viral activity. Local anesthetics, anticholinergics, and the anti-viral amines can be thought of as a pharmacological family. Inosiplex apparently takes advantage of some of those properties, and it too acts on the cell, rather than on the virus.[22]

The central inhibitory system regulated by gamma-aminobutyric acid, the GABA-ergic system, is protective against stress,[23–25] and ap-

pears to protect immunity by limiting the organism's recourse to cortisol, and by supporting the synthesis of alternative steroids.[26,27] Gamma-hydroxybutyrate and its lactone are closely related to GABA metabolic pathways, and have anesthetic and anti-stress protective effects which appear to result mainly from central inhibition, and from an anti-glucocorticoid effect. The lactone has been found to have a strongly protective effect against intra-cerebrally inoculated viruses,[28] and it is remarkably non-toxic. The anesthetic and anti-convulsant effects of progesterone probably synergize with and reinforce the GABA-ergic system.

Many other substances of low toxicity have beneficial effects on the immune system or on some other aspect of resistance, and might be considered in an integrated approach to immune restoration.

Just as optimal nutrition must take age and other factors into account, an integrated therapy for immune deficiency must be sensitively designed for the needs of the individual. In many places where AIDS-HIV patients are treated, a panic mentality has taken over, and ordinary supportive therapies are neglected or rejected because they are outside of someone's "treatment protocol." A stereotyped protocol can be appropriate when therapy is directed toward the mechanistically understood elimination of a pathogen, but in therapy to strengthen immunity, individualization, alertness, and judgment are more appropriate. The complex nature of every patient should be recognized, in deciding what materials to use and how to use them.

Resistance of the Heart

Townsend Letter for Doctors, June, 1992

THE heart gives us some clues to our general resistance to stress, aging, disease, and death. The heart and the brain are the most stress-resistant organs, and while moderate stress and malnutrition can cause the skin and thymus gland to lose more than 90 % of their substance, only the most prolonged and intense stress can cause the heart and brain to lose more than a fourth of their substance. In fact, a moderate stress that causes the thymus to shrink by more than 90 % can cause the heart to increase its mass by 80 %. When we are able to respond adequately and adaptively to stress, there is a transfer of substance from the lower-functioning organs (usually the skin and thymus) to the organs that are bearing the greatest burden, usually the heart and the brain.

The glucocorticoid hormones of stress play the important catabolic role of mobilizing substances from the "idle" organs to support the working organs. The many ways in which the heart is able to resist stress, and even to thrive on it, can be generalized to develop ways to protect other organs, and the whole body, from the chronic and cumulative stresses that lead to generalized atrophy, declining function, and aging.

During stress, the heart and other working organs become resistant to the glucocorticoid hormones. When a person is given radioactive testosterone, it can be seen to reach the highest concentration in the heart. It is testosterone's anti-glucocorticoid effect which causes it to enlarge skeletal muscles, when exercise is moderate. Its parallel effects on skeletal muscle and heart muscle can be seen in highly adapted (stressed) long-distance runners, since the walls of their hearts become thinner as their skeletal muscles become slimmer. The other anti-catabolic steroids, pregnenolone, progesterone, and dehydroepiandrosterone (DHEA), are present in larger amounts, and are of more general importance, than testosterone, especially in the brain, where their concentration is very high. Albert Szent-Györgyi showed that the heart responds to progesterone, and more recently other researchers have presented evidence that DHEA is our "endogenous digitalis."

During moderate exercise, adrenalin causes increased blood flow to both the heart and the skeletal muscles, while decreasing the flow of blood to other organs. The increased circulation carries extra oxygen

and nutrients to the working organs, while the deprivation of oxygen and glucose pushes the other organs toward a catabolic balance. This simple circulatory pattern achieves to some extent the same kind of redistribution of resources, acutely, that is achieved in more prolonged stress by the actions of the glucocorticoids and their antagonists.

Stress—a need for adaptation—can be seen as an "information gap" between the need and the possibility of meeting the need. Appropriate modification of the organism's structure closes that information gap. The new "structural trace," or memory, can develop as either a phenotypic or genotypic change. "Mutations" are important for bacterial adaptation, and learning is important for mammalian adaptation.

Stress physiology is now recognized as a universal and basic part of life, for plants and micro-organisms, as well as for vertebrates. Our brains are the newest and most powerful organs of adaptation and resistance to stress, allowing the simpler systems of circulation and metabolism to orient themselves appropriately to achieve the most benefit with the least damage. Just as there are pro- and anti-catabolic hormones and circulatory patterns, the brain has stress-promoting and stress-limiting systems. When perception and orientation govern the stress reaction, the ability to suppress certain parts of the reaction permits fine coordination and high efficiency. Sleep is a generalized stress-limiting function of the brain. Another example of how the brain governs the energy-mobilizing system in stress was demonstrated by Seligman: Rats that experienced "capitulation stress," being held still until they quit struggling, drowned in a few minutes when they were put into a tank of water. But a single experience of successfully struggling to freedom caused rats to swim for many hours before becoming exhausted.

A single experience, an insight, has tremendous power to shape the way in which a rat deals with stress. Insights and ideas can be gained through practice, but they can also be passed on culturally. We can learn how to prepare ourselves to respond optimally to stress, while also trying to keep the environment from becoming too stressful.

Blue-collar workers have more heart attacks than do sedentary workers, and the "biosocial" stress of low status can be seen as a powerful factor in mortality from heart attacks. The helpless feeling of low status is analogous to capitulation stress. When stress is strong enough and long enough to overcome the multiple protective systems of the heart, the heart fails in certain well-defined ways, both functionally and

structurally. But before injury occurs, the stress-limiting "self-restraint" systems of the heart, of the endocrine system, and of the brain, will have to fail. Considering some problems of blood circulation will help to see the integral nature of adaptation, when it succeeds and when it fails.

Pregnant women sometimes develop very high blood pressure. In the 1950s, when new diuretics were being promoted by the drug companies, it became standard practice to give pregnant women diuretics and a low-salt diet to control their blood pressure. It should have been obvious (and it was obvious to people like Tom Brewer who thought physiologically, rather than mechanically) that the increase in pressure was the body's response to an increased need for circulation. As the fetus grows, the blood volume must expand, to meet the increased circulatory needs of the uterus, placenta, and fetus. Two research projects showed that very large supplements of salt reliably normalized the high blood pressure in women with "toxemia" of pregnancy. Other studies showed similar results with a supplement of progesterone. When the blood volume is able to expand as needed, circulation is adequate at normal pressure. When blood pressure is forced down by administering a diuretic to further diminish an already inadequate blood volume, the circulation of oxygen and nutrients to the fetus is seriously impaired, and a huge epidemic of mental retardation and hyperactivity, associated with low birthweight, began in the 1950s, and continued until eventually the fear of malpractice suits stopped the absurd practice.

A few years ago I asked a recently graduated physician what things he would want to consider in a patient with high blood pressure. Some of his suggestions for therapy were very reasonable, but his approach made it clear that he was thinking of circulation in a mechanical way, exactly as a skilled plumber would go about normalizing the circulation of water, without caring very much about what the water was being used for. The circulation of blood is nicely adjusted to meet the demands of the tissues. Blood pressure increases gradually with age, and individuals whose blood pressure stops increasing with age have been found to have a shorter life-expectancy than normal. Apparently, aged tissue is less efficient, and needs a more strongly pumped stream of blood.

When I found, around 1970, that the pressure of oxygen was low in old animals and in animals that had been treated with estrogen, I tried to determine the reason for the oxygen deficiency in each case. I found that in old individuals (hamsters or humans) the blood was only

about 50 % oxygenated as it passed through the lungs, as if diffusion into the capillaries was impaired. Estrogen treatment (rats and humans) does the same, apparently by causing a sort of edema that thickens the lung tissue through which the oxygen has to diffuse. Both estrogen treatment and age cause other inefficiencies in oxygen transport and inefficient use in the tissues, further exacerbating the shortage of oxygen. Interestingly, recent studies show that "capitulation stress" causes the same variety of problems in oxygenation, transport, and use. In stress, even the respiratory center of the brain becomes under-active, tolerating the state of hypoxia. Since progesterone activates the respiratory center, the depressed respiration of stress is consistent with a deficiency of progesterone.[†]

When tissue oxygenation is inadequate, glucose is depleted quickly. In prolonged stress, the liver's gluconeogenic response to the glucocorticoids is depressed, as is its ability to form and store glycogen. As glucose is less available, the amount of adrenalin in the blood rises, and fat is mobilized from storage as a substitute source of energy. Free fatty acids, especially unsaturated fats, are toxic to the mitochondrial respiratory system, blocking both the ability to use oxygen and the ability to produce energy. The increased use of fats, instead of glucose, causes lipid peroxidation to increase, and promotes the release of lysosomal enzymes, the accumulation of calcium in mitochondria, the depletion of ATP and creatine phosphate, and a failure to "pump" calcium out of the cells, causing incomplete relaxation and rigidity of the heart muscle cells.

This complex of effects can be called "catecholamine toxicity." Rona, et al.,[1] using isoproterenol in 1959, clearly established the existence of this toxicity. Several years ago, it was noticed that mortality in the U.S. from asthma increased greatly in the years since catecholamine therapy became common, without a corresponding increase in the incidence of asthma. It is now widely accepted that the therapy caused the increased mortality. Following Rona's work as it did, this large medical experiment can be taken as strong confirmation of the idea of catecholamine toxicity,

[†] The consistency with which oxygen becomes deficient in aging, stress, and estrogen excess suggests that a basic coordination mechanism may be involved, in which there is a shift toward the conditions which will activate the expression of certain genes—possibly the hypoglycemia-stress-heat-shock proteins, or possibly simply the proteins of cell division and growth.

and as a step in understanding stress sickness. Glucose depletion leads to adrenalin secretion, which causes fat mobilization, calcium-activated over-stimulation of cells, with impairment of the energy production which is necessary for recovery (by way of muscle relaxation and calcium excretion, etc.).

Broda Barnes showed that hypothyroidism causes heart disease, and also causes a tendency toward hypoglycemia. Low thyroid people compensate for the deficiency of energy and glucose (and of oxygen, for reasons similar to those mentioned above) by secreting an excess of adrenalin. Their 24-hour urine metabolites of adrenalin sometimes are 30 or 40 times normal. Recent studies that show that a moderate dose of thyroxin lowers lipid peroxidation confirm that thyroid has an anti-stress effect. The "conduction block" which occurs in hypothyroidism seems to be the same as the conduction block which develops in stress and predisposes to fibrillation. The electrical instability of the heart produced by excessive adrenergic stimulation can also make the sinus pacemaker more susceptible to vagal inhibition. (I think this effect can be observed in the skipped beats often experienced by hypothyroid people during stress or fatigue. In other situations, of long and intense stress, vagal stimulation protects against fibrillation.)

In hypothyroidism, there is impaired relaxation of muscles, as seen in the Achilles reflex, or in the T wave of the electrocardiogram. This is similar to the contractural rigidity which develops in the stressed heart.

When stress is severe and prolonged, the liver loses enzymes of the detoxifying system, and also of the system that forms bile acids, causing a tendency toward abnormal lipid metabolism, including hypercholesterolemia. Thyroid deficiency limits the consumption of circulating cholesterol for steroid hormone synthesis, and both stress and hypothyroidism are associated with elevated blood cholesterol. Considering the clear and well-defined toxicity of adrenalin and free fatty acids, the role of cholesterol in heart disease begins to look sort of epiphenomenal.

Fats enter and damage cells that are over-stimulated and de-energized.

Calcium is a universal activator, but excess calcium is the central link in most types of cell damage. Calcium uptake and retention are promoted by adrenalin, histamine, vasopressin, energy depletion, and lipid peroxidation and by the activity of phospholipases; since calcium can activate phospholipases and lipid peroxidation, and interferes with

energy production, vicious circles can develop. Excessive adrenalin and calcium also promote clotting, and—as the beta-adrenergic receptors become desensitized—spasms in the coronary arteries. Altered blood vessel tone, which can be produced by serious stress, can cause venous pooling of blood, which synergizes with the impaired relaxation of the heart to cause cardiogenic shock.

There are several systems that oppose the toxic effects of adrenalin. GABA, dopamine, and adenosine have multiple anti-adrenergic effects. In many situations, the parasympathetic system is protective against adrenalin. The protective steroids also act at many levels. Magnesium, retained in the cell largely under the influence of ATP and thyroid, is our basic "calcium blocker," or calcium antagonist. GABA and dopamine inhibit the ACTH-glucocorticoid system, and shift the steroid balance toward the protective anti-glucocorticoids, progesterone, testosterone, pregnenolone, and DHEA.

Adequate glucose and oxygen are the most important anti-stress substances. "Overload" of an organ means that the blood isn't delivering enough oxygen and glucose to sustain the needed level of functioning. Thyroid and progesterone tend to prevent overload by increasing respiratory efficiency, and by increasing the liver's glycogen storage.

Uridine, a co-factor in glycogen synthesis, can also prevent stress by improving glycogen storage.

Anti-oxidants, especially vitamin E, prevent tissue damage by promoting normal oxidation.

Selye's demonstration of corn oil's toxicity to the heart is an important link in the general picture of stress injury and adrenalin toxicity. The protective effects of saturated fats are not surprising when seen against the background of the toxic effects of adrenalin, causing the mobilization of fatty acids and the resulting lipid peroxidation.

Meerson's demonstration that gentle adaptation to hypoxia (similar to treatment with thyroid hormone) can prevent heart damage from subsequent intense and prolonged stress, is similar to Seligman's discovery that rats can be protected against stress by an experience of escape, but Meerson has surveyed a great range of protective processes, ranging from the subcellular level to the most highly evolved brain systems. In thinking about Meerson's achievements in protecting the heart against stress, it is important to remember that the heart is our most stress-resistant organ, and that the things that protect the heart from deadly

stress will also protect the other organs from the everyday stresses, which accumulate to cause the problems of general aging. Liver, lungs, pancreas and other essential organs are susceptible to the same kinds of damage as the heart, but under conditions that are relatively mild and ordinary.

The resistance of the heart and liver can be compared in several ways. For example, DNA replication is more easily suppressed by stress in the liver, than in the heart, but DNA repair is not affected in the same way by stress. Hyperfunction of the heart stabilizes DNA against injury, so DNA repair is greater in the liver than in the heart, and is least in the brain.

Meerson's laboratory has studied the anti-stress and anti-adrenalin effects of GABA and its metabolite, gamma-hydroxy butyrate, especially in the form of the lithium salt. (Lithium seems to have its own anti-stress effect, probably partly as a sodium agonist, and partly through its ability to complex with the ammonium which is produced in the brain in fatigue, which is exactly when the GABA system becomes active.) GHB is protective against stress damage to many tissues. It prevents stress-induced enzyme leakage from tissues, ulceration of the gastric mucosa, lipid peroxidation, epileptic seizure, damaged contractile function of the heart, and cardiac arrhythmias produced by stress or ischemia.

Meerson's group has also studied the protective effects of the gamma-butyrobetaine derivatives of the sort that are normally produced in the brain and heart, or that have been synthesized or extracted from plants. These substances stabilize the heart rhythm in acute myocardial infarction, and also in postinfarction cardiosclerosis.[2, p. 173] They have a protective action against both adrenalin and calcium. Interestingly, atropine potentiates the protective effect of the butyrobetaine against calcium toxicity.

A complete list of protective nutritional chemicals and natural drugs or analogs to our endogenous protective factors would be very long, but we should give special thought to certain ones, including succinic acid, which stimulates respiration and protective steroid synthesis; thyroid and vitamin E, which promote normal oxidation while preventing abnormal oxidation; magnesium; sodium and lithium, which help us to retain magnesium; tropical fruits, which contain GHB; coconut oil, which protects against cardiac necrosis, lipid peroxidation, hypothyroidism, hypoglycemia, and histamine damage; valium agonists, natural anti-

histamines; adenosine and uridine. Visits to higher elevations, and exposure to bright, long-wave light, can cause the body to optimize its own anti-stress chemistry. Avoiding the sense of being trapped is a high-level adaptive factor.

The life-span of cell organelles, DNA, and essential enzymes, is extended by adaptation. The cellular (membrane phospholipid) composition adjusts toward a lower content of unsaturated fatty acids.[3] Diacylglycerol causes activation of transcription, cell growth, and proliferation.[4] Stabilization of mRNA splicing and protein synthesis[5] suggests the possibility that this system might also be important in viral immunity.

P.S.: Pavlov's turn-of-the-century work on the heart's "trophic nerves" should be re-examined in the light of this new information on the trophic effects of adaptation.

Response to Dr. Davis

Townsend Letter for Doctors, November, 1995

THANKS for passing on the comments from Dr. Davis, PhD. I haven't received his letter asking me for references, and I assume it's because my Mexican address was listed with the coconut oil article. (I'm back in Eugene, Oregon).

Davis mentions that he looked in Medline for references to the animal studies I wrote about. Practicing physicians, who put in long hours with their patients, and who work in the context of an often authoritarian profession and an oppressive bureaucratic culture, need to find out in an efficient way what other physicians are doing, and they probably find Medline and Index Medicus very useful. But for a research scientist working in a college of natural sciences, in a university with a good library, there are more appropriate ways to search—especially since I emphasized that some of the work was done more than 50 years ago.

I decided to take a random sampling of Medline's information. (I noticed that the library's machine advised that Medline not be used if you are looking for information on non-human animals). I looked at their entries for 1984, where I found F. Bershauer, et al.:[1] "[Fat content in the coconut oil fed animals, after only 34 days, was 15.9 %; in the control group, 18.6 %; and in the sunflower oil fed animals, 21.1 %]."

So, I saw that Medline does include an animal-nutrition journal, and decided to check another year. J. Yazbech, et al.[2] suggested that the observed increase in resting metabolic rate produced by using coconut oil to create an essential fatty acid deficiency, is partly the result of increased heat production in the brown adipose tissue. The weight of that fat decreased by 28 %, while its ability to produce heat increased 69 %.

If Davis checked a data-base that was designed for animal research, he could find an abundance of publications relevant to the question of coconut oil's effect on body fat. I don't know of any computerized data systems for biology that go back 60 years, but manual searching of the printed sources is only a little slower than the electronic method, and infinitely more precise. Over the years, I have noticed that science libraries seem to be off limits to most professors, so any information they can get from computers should be significant, but the reliance on

computer-retrieved information puts an awful burden on the people who choose the keywords.

The *Townsend Letter*, especially with your new title, is obviously a journal of viewpoint, and not of technical data. As such, much of its function is to clarify goals, orientations, and beliefs, and possibly to encourage people to have more imaginative, flexible, and critical attitudes toward medical ideas. When a publication purports to be objective and "scientific," then there is a problem with unsupported assertions. If Davis had complained, for example, that an article in the *Scientific American Science and Medicine* by D. V. Spicer and M. C. Pike[3] was doctrinaire, ideological, and promotional, and failed to support most of its important assertions, I would think his letter was constructive. But I think he misunderstands the *Townsend Letter*'s reason for existence. Although it isn't at all the sort of "alternative health" journal I have imagined publishing, its openness is important in this increasingly repressive medical-bureaucratic environment.

The refereed journals are not great critics of themselves. Some appalling things happen at the "great journals," but the scientific-medical reader generally assumes that the editors fairly select representative experts to review the submitted work. Venality, bigotry and plagiarism are probably just as well represented in the main-line professional journals as in other parts of our society. The greatest abuses are possible when the referees are anonymous. A series of shocking experiences with journal referees over a period of 15 years led me to stop submitting my work to professional journals in the U.S. There are only a few small journals that I think are respectably free from the corrupting influence of corporate power.

In 1981, I began a newsletter to keep my friends informed of my progress. Occasionally, these almost private communications get wider distribution, as when the *Townsend Letter* picks them up. I am glad to offer a few readers some background sources and occasionally some additional material I didn't cite in the newsletter, but when someone is making their first approach to an area of research, I think the best method is to ask a science librarian to help them.

Response to Recent Pop-Medicine Articles on Progesterone Therapy

Townsend Letter for Doctors, 1984

SINCE 1940, it has been clearly established that estrogen is carcinogenic in every species studied. Shortly thereafter, studies appeared suggesting its possible involvement in heart disease. In 1950, I heard physicians warning about the risk of cancer when estrogen is used medically. The increased use of estrogen in the face of such evidence is, I believe, a process unique in medical history and is nothing but shameful for all who are involved.

By 1950, many studies had demonstrated that progesterone can protect against the effects of estrogen, including cancer. By that year, progesterone was shown to prevent estrogen-like and testosterone-like actions. Often, they suppress the formation of progesterone in the body, and in such cases could be called "anti-progesterone progestational agents." There is no justification for confusing progesterone with any synthetic steroid. When someone with access to the data confuses them, we must suspect their motives or their qualifications.

Progesterone has a unique position in physiology, partly because of its intrinsic range of hormonal activity and partly because it serves as a precursor for all the other types of steroid hormones. The concentration of progesterone which occurs during pregnancy is uniquely high among all hormones and requires a balance of intrinsic properties such that the physiology of the organism is protected, rather than thrown out of balance, by such high concentrations.

In spite of the toxic effects of even natural estrogens, multiparous animals and humans have a lower cancer incidence than do nulliparous individuals and apparently a longer life expectancy. These effects have all been related to progesterone.

Opponents of progesterone therapy are searching for new strategies, in addition to the standard "it's all in her mind" approach to women's symptoms. The ideology that pregnancy is a disease is being brought into service in this new conflict—women are being threatened with the thought that progesterone will make them feel pregnant, as if healthy pregnancy should cause undesirable feelings. One of the oldest warnings, and probably the most interesting, is that progesterone can produce

feelings of euphoria. Less amusing is the totally false new threat that women may become progesterone addicts.

Reading some of the anti-progesterone literature gives one the impression that many doctors are suddenly going to reject the use of any medication which requires the adjustment of dosage to suit the patient's response. After discussions of how unscientific it is to use progesterone in dosages varying between 200 mg and 2000 mg per day, a writer in *Medical Month* says that: "…Absence of standard dosages troubles observers on both sides of the therapeutic fence. 'It's trial and error,' says Nathan Kase."[1]

Just to the left of that quotation, there is a half-page advertisement for a tranquilizer, saying "Trust Tranxene," which comes in scored tablets of 3.75 mg, 7.5 mg and 15 mg, and in 22.5 mg "single dose tablets." A scored tablet of 3.75 mg suggests a possible dose of less than 2 mg, and a "single dose" 22.5 mg tablet indicates a dose about twelve times larger. This article, *Dangerous Fad Therapy for Premenstrual Syndrome?*, defines progesterone as "cholesterol derivative," very likely to get a little extra propaganda value from associating it with the cholesterol scare. In fact, all natural steroid hormones are derived from cholesterol. (I wonder how such a sleazy article as this finds its way into physicians' waiting rooms.)

A new pseudo-medical campaign is under way, against the use of natural progesterone therapy in premenstrual syndrome. This campaign is likely to intensify as new, efficient and effective forms of progesterone become available.

Response to Tim Zell

Green Egg, Volume 5, Issue 51, 1972

I have just read *Green Egg* 44, and have comments on several things in it. Immortality of the body will resolve the disputes about what constitutes survival of the personality. To achieve it, we have to know what the "intrinsic" causes of bodily deterioration are, inaging. When growth stops, most differentiation of cell function stops, and soon dedifferentiation and cell death begins. Anything that interferes with energy production promotes the process: damage leads to thickened connective tissue, which limits diffusion of oxygen, which causes more damage. In youth and health, cell water is "liquid-crystalline," or ordered, and this order causes the "cell sap" to retain potassium and exclude sodium. Anything that lowers the energy charge of the cell causes the water to "melt" or become disordered. When dedifferentiation is complete, division is all the cell can do: wasting from cell death, and cancer are two outcomes of "aging." Progesterone and testosterone, two very similar female and male hormones, promote differentiation. Estrogen (men have about as much as women do except for a peak following ovulation) dedifferentiates, and promotes all the known processes of aging.

Experience modifies cell water (especially in nerves), and so is intimately involved in development of tissue: a stimulating environment causes brain growth in rats, body ratio correlates with a long brain/ Acquired brain size happens to be inheritable, at least in rats. (These data are all American, published in the most respectable journals. The Russians for a long time have had an attitude toward matter—even in the 19th century—that makes them more respectful than the average Western person of the abilities of matter and organisms, and better able to have richly varied perceptions about nature. The mechanistic-Cartesian western tradition of science tries to dominate "passive matter" and distains, ignores, or steals the real achievements of the Russians whose claims to have invented just about everything turn out to be true, if you study sources rather than western review articles.)

These data (and many more) imply that "culture," in a very specific sense, reflects and limits bodily evolution, development and life-span, as well as having its more obvious affects on consciousness and behavior. Discovery and high generality of knowledge contribute to renewal of the

body bodily flexibility and sensitivity are an aspect of "high generality of knowledge." Cellular, behavioral, and intellectual complexification require participation in a richer culture. Sexuality is an important part of this evolution-for-survival: consider the idea that orgasm is always a discovery-perception of newness. The minimum immortal unit is apparently a sexual-intellectual couple. There are vitamin-mineral-hormone-manipulation technologies that delay aging, but awareness is essential to stabilize the complexification.

Instead of eugenic selection, we are left with the personality more complex and rewarding responsibility for growth.

It is probably through modifications of cell water that attitudes can change enzyme function, response to drugs, intensity of consciousness, etc. Palladin, a famous Russian enzymologist, has shown many effects of awareness on enzyme activity.

Kozyrev's ideas on time and organismic "handedness," etc., are probably closely related to the microstructure of cell water. Incidentally, the hemispheric spin effect is mostly mythical: it was only recently that someone finally managed to design a very big, highly insulated vessel that would consistently show a hemispheric spin; the bathtubs etc., depends on shape of the tub, small currents, etc. a good example of how a good theory can persist in spite of many years of non-confirmation. Dror Sadeh, while working in Washington, DC, did some experiments that confirmed Kozyrev's "wildest" suggestions. He mounted a cesium clock on a truck and compared its signal with that of a fixed clock in Washington; as he drove up and down the coast, the distant clock showed a "red shift," corresponding to 1500 miles (he went as far as Maine, about 1500 miles away). The distant clock operated more slowly, or radio distance altered the frequency of the radio signal; the effect began at sun-rise, and continued through the day; he observed a similar effect in star-light passing close to the sun. This spoils the red-shift argument for the expanding universe, and also changes the probable meaning of the circumnavigated cesium clock that was supposed to confirm the existence of a relativistic "twin (or clock) paradox." They support Kozyrev's contention that time is a form of energy and organization (negative entropy). There is a developing link between these ideas and those of the Russians who maintain that telepathy and PK use a kind of energy that is not electromagnetic. H. C. Dudley is working on the implications of a universal, isotropic "neutrino sea," which among other

things forms a link for nuclear interaction at a distance, and serves as an "ether" for transmission of electro-magnetic energy. Nuclear decay, for example, turns out to be an equilibrium process not a "constant," and is subject to alteration by such things as molecular order. His most recent work will appear in the physics journal *Nuovo Cimento* soon.

The Kirlian effect itself doesn't seem to involve anything but a visualization by a high frequency alternating "corona discharge" of conductive regions in and around the organism; an understanding of the conductive medium electronic resonance, or "neutrino sea," or whatever is a problem that has been recognized by many others. Hormones, radiation, emotions, etc., cause such changes of tissue conductivity and charge distribution, that can be detected with a Burr microvoltmeter or more common instruments.

If we can avoid a compulsive answering too-soon, and assimilate a very great variety of experiences, high generality interpretations will eventually become possible.

Rosacea, Rhynophyma, Pterygium & Riboflavin---& Varicose Veins

Townsend Letter for Doctors, July, 1987

SEVERAL times lately I have heard that the cause of rosacea is unknown; for example, in Dr Donohue's newspaper column, he wrote that "we don't know the precise cause," but then said that "hot beverages and spicy foods can contribute to such enlargement; so does alcohol." For many years I have assumed that the cause was known to anyone who cared to know, so I think it might be useful to describe some case histories, and some processes that relate to the cause.

In 1964 a somewhat alcoholic neighbor of mine was interested in improving his memory, since he had trouble finding the words he wanted when speaking or writing. His nose was remarkably red, but at the age of 41 or 42 it was not noticeably enlarged. I suggested many times that riboflavin might help, since I inferred from his very vascularized nose that his tissues were experiencing relative hypoxia, and that his brain tissue might be suffering even more than his nose, since such extensive new growth of blood vessels would seem less likely throughout the brain. For several weeks, he kept coming back asking me to remind him what it was that I had suggested; I started giving him notes, but he mislaid them. Finally he retained one of the notes long enough to ask his doctor to give him some vitamins, and the doctor prescribed daily injections of the vitamin B complex. I saw him in the afternoon a few hours after his first injection, and was surprised to see that his nose was no longer red; he spoke fluently and quickly, and did not have to search for words. Each day that week he returned for more injections, and both his nose and his memory stayed healthy. However, over the weekend, when the doctor's office was closed, both problems returned in full: his nose was as red (and shiny) as ever, and he struggled for some word in almost every sentence. By Monday it seemed that he had forgotten the whole episode, and didn't return for more injections.

I moved away around that time, and didn't see him again until 1976. At that time, his nose didn't seem particularly red, but it had enlarged and become very lumpy—a potato nose, or rhynophyma. (Rhynophyma is considered to be an advanced, hyperplastic form of rosacea.) He had

undergone surgery for defective heart valves, but seemed to be in good health except for occasional nosebleeds. (He died in 1985.)

Before learning that he had nosebleeds, it had occurred to me that bloodshot eyes and a red nose probably have internal equivalents, which might be revealed as nosebleeds in some individuals, and as strokes in others. I knew a woman whose four year-old son had very frequent nose-bleeds that usually occurred around one or two AM during sleep, or during daytime naps. He also had frequent violent rages, that seemed to happen after he had eaten certain foods, usually cookies or cake. I reasoned that a riboflavin deficiency would waste glucose by blocking mitochondrial respiration, and that blood vessels would dilate to deliver more blood to the tissues. Since blood sugar falls at night, I thought this could account for the regularity of his night-time nosebleeds. His frequent angry behavior seemed to be an exaggeration of the normal irritability of hungry children. His mother had some distinct mental problems, which had included a classical postpartum psychosis. She wore contact lenses, and I noticed that she had chronically visible blood vessels in her eyes, mainly on the side toward her nose. The area was yellowed, and lumpy. Close inspection suggested that the vessels had become increasingly enlarged, numerous and tortuous, until the surface of the eye was distorted by the excess of blood vessels.

The cornea normally has a high concentration of riboflavin, but it is very susceptible to a deficiency of that vitamin. It receives its oxygen largely directly from the air, and partly from the ring of blood vessels at its edge, which are supplied by vessels approaching from the two sides. In her case, it seemed that the contact lenses, shutting off direct contact with the air, had led to an invasive growth of blood vessels to the edge of the cornea, probably partly because of a riboflavin deficiency.

I think this would be called a pterygium, but I think the same kind of process would be called rosacea if it occurred on the nose or cheeks. Oxygen deficiency causes connective tissue cells to produce extra collagen. This would intensify the problem of delivering oxygen to the cells, tending to set up a vicious circle. Even normal levels of riboflavin and other nutrients and oxygen in the blood wouldn't be enough to allow the necessary amount to reach the cells, once the lumpy fibrous overgrowth had begun to develop.

I gave the woman and her son each 10 mg of riboflavin one morning, and suggested using that amount for a few weeks. The boy's nose didn't

bleed that day or in the night, and as far as I know, it never bled again. He stopped having his fits of rage. Several years later his mother became chronically insane; I believe her heavy smoking, a poor diet, and an increasing hormone imbalance, were probably causing an increasingly severe energy deficiency in her brain. In that organ, as in the heart and lungs, androgenic steroids and other anti-glucocorticoids such as progesterone, are probably responsible for a normal resistance to atrophy during starvation. However, girls suffering from anorexia nervosa do sometimes have demonstrable shrinkage of the brain (which can be reversed by good nutrition) showing that the brain is not absolutely protected from catabolism, especially when the steroid hormones are out of balance.

The brain seems to be extremely resistant to the overproduction of fibrous tissue, unlike the exposed tissues of the eye and nose. There are some degenerative brain diseases, though, in which the supportive glial cells are overproduced. This may represent a basic stress-reaction, not so different from that which occurs in potato-nose and pterygium.

Although I have seen nearly instantaneous effects of a small dose of riboflavin, I want to emphasize that the enlarged and invasive blood vessels caused by a deficiency of that vitamin will not necessarily go away even with prolonged supplementation with riboflavin. I believe that the delicate red blood vessels that often first appear around the nostrils, and the larger red, purple and blue vessels that usually appear on the sides of the feet below the ankles, and more obvious varicose veins, can also result from loss of tone in the walls of the blood vessels, in addition to any overgrowth process that might be occurring, and that various problems related to stress and nutrition can be responsible. I have seen very distinct blood vessels disappear completely after using thyroid and oral DHEA. I think this is partly the result of restored muscle tone, as can sometimes be seen in the blood vessels of the hands shortly after taking progesterone.

Many people who have taken a course in physiology think that arteries and arterioles are the only blood vessels containing smooth muscles because of the odd over-emphasis that is usually given to the contraction of arterioles. In fact, I feel that the conventional theory about the role of arterioles in regulating circulation is wrong. It is usually assumed that the capillary wall and the endothelial cells are not contractile, and this

idea, with the assumption of passive veins, creates the impression that "peripheral resistance" is only the result of arteriolar tone.

Many veins are very well-supplied with smooth muscle. When the physician scoffs at the idea that varicose veins could "recover," it is because of the idea that "they occur when the valve fails." Since the valve is just a flap of tissue, it is hard to imagine how it could be restored. But if you realize that veins (especially the subcutaneous veins which become unsightly varicosities) are well-muscled, you can see that a loss of muscle tone will lead to swelling of the vein, and that a valve which could close a small channel, simply can't reach across the channel of a distended vein. That is, valve failure will necessarily follow loss of smooth muscle tone. If the tone is restored, the channel will return to its normal size, and the valve would have a chance to function again.

Although major structural restorations can occur in many tissues, even in middle-aged people, when conditions are favorable, it is much better to stop degenerative processes before they have gone very far, by optimizing all aspects of the environment, as far as this is possible.

(Synthetic riboflavin is allergenic, so natural sources are the safest.)

Sales Pitch for Linseed Oil

Townsend Letter for Doctors, February/March, 1989

YOUR publication performs an important service in allowing the free expression of ideas in medicine and related subjects. Many publications, contrary to the spirit of science, "protect" their readers from improper ideas. Too many publications are actually protecting their advertising revenue by rejecting criticism of certain drugs or food supplements. Industries with annual profits in the billions of dollars have the power to control medical journals, professors of medicine, and public opinion. *Townsend Letter for Doctors* is one of the few publications which has allowed criticism of the idea that our diet should be supplemented with the essential fatty acids.

The article in your December issue by Mike Minarsich, and the book review excerpt by J. S. Bland, Ph.D. call for some special criticism. Minarsich is obviously a linseed oil salesman (president of New Dimensions Distributors), and he takes his pseudo-facts right out of the book by Udo Erasmus, so my comments are mainly about the Erasmus book, and some of its ideas which are derived from the "scientific work" of Johanna Budwig.

Dr. Bland's review excerpt says "Fats and Oils is filled with interesting and accurate information…" and "is the first complete guide to everything you need to know about fats, oils and cholesterol to make the right food choices for your health." T. H. Huxley said that book reviewers too often get all their information on the subject from the book being reviewed, like the Abyssinian who supposedly took his steaks from the same ox he was riding; but it is hard for me to believe that Bland has really read this error-filled, incompetent, and possibly deliberately misleading book. If Udo Erasmus is a hired commercial writer working from information provided by his employer, then he has done a smoothly competent writing job, and it is the publisher who misleads by failing to give some background information.

Judging by the book, I suspect that neither Erasmus nor Budwig has studied the fundamentals of organic chemistry. That isn't important. But it is very important that linoleic acid, and related oils, in the amounts recommended by Udo Erasmus, are known to cause:

- impaired brain development and learning;
- damage to skin and bones;
- accelerated aging and age-pigment accumulation;
- damage to the circulatory system;
- increased cancer incidence;
- suppressed immunity;
- endocrine dysfunction.

U.S. consumption of seed oils had been almost doubling every decade since the first world war, but the technological advances of the 1960s which allowed paints to be made from petroleum derivatives, rather than from linseed oil, safflower and soy oil, stimulated the redirection of large amounts of these substances from paint production into the food market. Clever marketing tricks are in some cases creating price mark-ups of 10 000 %. I spoke to a dealer who said he recognized the toxicity of linseed oil and wouldn't use it himself, but that the profit was so big he was going to keep selling it.

An acquaintance who died recently after several months of eating large amounts of linseed oil told me that it had been used by both W. F. Koch, M.D. and Max Gerson, M.D. I knew this wasn't true: For example, Gerson's program evolved from a diet for migraine and tuberculosis into a cancer therapy, and involved the use of thyroid extract, liver, fresh juices, and a little butter, but over and over he said "absolutely no oil."

My friend sent me a page from Gerson's book, containing the recommendation for 1 tablespoon of linseed oil. My copy of the Gerson book, published while he was alive, contains no such statement on that page, but rather the phrase in bold capital letters, NO OILS! My informant also assured me that Gerson had known Budwig and respected her work. Gerson's book contains detailed discussions of all the main dietary approaches to cancer, with a large number of references to the scientific literature, and it did not mention Budwig at all. Since Budwig's proposals are diametrically opposed to Gerson's he would have had to account for them if he had known of them.

The people who are using Max Gerson's name and reputation to sell linseed oil are harming the people they mislead, and are dishonoring Gerson's important work. The altered book is going to boggle the mind

of any thoughtful student who tries to understand what Gerson was really doing.

Minarsich and Erasmus similarly invoke the names of several great biochemists in making their sales pitch for linseed oil. Any serious student of biochemistry will recognize the absurdity of their outline of biochemistry, but the average reader is likely to swallow the idea that Ms. Budwig represents the culmination of a century of scientific progress. Dale Alexander made a career of the idea that cod liver oil will grease arthritic joints. Now a generation later, the vast food oil industry has a slightly higher class of sales promoters. It is urgent that we start developing a more critical medical-scientific culture.

Research showing the toxic effects of unsaturated oils goes back more than 60 years. A 1985 article published in my newsletter cites some of the key references.[1, p. 41] These substances inhibit many enzymes (e.g., in digestion, in immunity, in clot removal, in thyroid function), they disrupt mitochondrial energy production, and they interfere with communication between cells. We hear very little about these toxic effects, and there is not much money available for more research in these areas. Naturally, these topics aren't mentioned in the Erasmus book. The "toxicity" questions treated in the book do not include the toxicity of fresh and natural unsaturated oils, and so they have the function of a red herring, distracting the reader.

For nearly 20 years, mainline medicine has advocated the use of unsaturated oils "to protect the heart." A few scientists, like Hans Selye, kept telling the (contrary) truth. Now big business has many people in "alternative medicine" falling for the false establishment story.

Sharks, Salmon & Osmotic Therapies

Townsend Letter for Doctors, July, 1991

In the 1960s, I met Leonell Strong, the geneticist who developed a famous strain of mice that are extremely susceptible to breast cancer. My first research in endocrinology had to do with their estrogen metabolism, and ways to normalize it. Strong (who studied genetics with T. H. Morgan) was interested in the fact that sharks are not susceptible to cancer. As a geneticist, he saw this in relation to their "genetic stability," that is, the fact that they haven't developed beyond an early stage of evolution, and he believed that cancer is a result of genetic instability. He found that injections of an extract of shark's liver prevented mice from developing breast cancer; however, similar extracts from other kinds of liver had similar effects on the mice. Since his mice had too much estrogen, I supposed that their livers were deficient in something needed to eliminate estrogen, since the liver normally is a powerful regulator of estrogen, using a certain system of "detoxifying" enzymes. (As it turns out, the thyroid hormone is the basic regulator of this detoxifying function.)

As I studied estrogen in other situations, two features of its action stood out—it interferes with respiration, and it causes cells to take up water. Its other effects seem to follow from these. In the 1920s, it was found that hypotonicity, an excess of water, stimulates cell division (while hypertonicity inhibits it). Around 1940, Hans Selye found that estrogen's systemic effect mimics the shock phase of the stress reaction. In shock, deficient circulation of blood and thus deficient oxygenation of tissue are the main problem, and Selye considered the adrenal steroids to be crucial in resolving the problem, and creating adaptation to the stress. But the adrenal steroids can have their own undesirable consequences.

Sharks, besides being primitive and not suffering from cancer, are physiologically unique in another way: their body fluids are osmotically in balance with seawater, making them hypertonic to other animals' body fluids. The mineral content of sharks' blood is not very different from that of other animals. The osmotic difference is made up by a very high concentration of urea (and of trimethyl ammonium). In general, animals that live in water are able to get rid of ammonia easily, because it is very soluble in water, and the excretion of nitrogen as urea and

uric acid is considered to have evolved to avoid the toxicity of the large amount of ammonia that would otherwise accumulate in land animals. Therefore, it seems that sharks' urea evolved as a kind of osmotic buffer (rather than as an excretory product), keeping them in osmotic balance with ocean water, without having to deal with internalization of the extremely high (3.3 %) sodium content of ocean water.

Another kind of fish, the salmon, which return to fresh water for reproducing, show the other extreme of adaptation to an osmotic problem. After living "isotonically" in the hypertonic ocean environment, keeping their mineral content and osmolarity lower than sea-water's, they suddenly have to readapt to the extremely hypotonic fresh water. The secretion of prolactin and glucocorticoid steroids seems to facilitate this sudden adaptation, but those hormones also seem to produce an explosively rapid kind of aging. I think their condition is similar to the "Cushingoid" symptoms that frequently appear in middle-aged people.

Highly energized cells can resist the osmotic stress of too much water in their environment, and tired cells can't. Removing the stress, by making the surrounding fluid isotonic or slightly hypertonic, can protect the cells' energy level, and give them a rest. Until about 1940, the use of hypertonic solutions in therapy was fairly common. Books still mention the use of urea, USP, as a diuretic to treat brain swelling, but I haven't heard that it is still used this way in the United States. Veterinarians sometimes use hypertonic urea to treat uterine inflammation and infected wounds. Early in this century it was often mentioned as a safe disinfectant and promoter of healing for wounds. It was sometimes used as a powder, and was sprinkled pure onto skin grafts or between bone fragments in repairing fractures. Although it caused some pain, people generally thought it accelerated healing while preventing infection. (Typically, 5 g of powder would be dosed into the wound; milder treatments would probably have been possible, but wartime conditions didn't foster subtlety in medical research.)[1]

Hypertonic sodium chloride (Clifford White, *Lancet*, October 30, 1915) was also used to treat infected wounds, and its success in treating war wounds led to its use as a vaginal douche in treating various inflammations and infections, including infections associated with childbirth, salpingitis, cellulitis, gonorrhea, vaginitis, and erosions of the cervix, and in preparing a cancerous cervix for surgery. Irrigation of the abdomen with the saline solution gave good results in acute infections

that required abdominal drainage. White used a solution containing 1/2 ounce of sodium chloride and 1/16 ounce of sodium citrate in a pint of water. M. Englaender[2] used intravenous injections of 100 mL of 2 % NaCl to treat a variety of infections and inflammations.

In Russia, Gubin[3] treated sciatica with two glasses of warm water containing 1.4 teaspoonfuls of NaCl, placed in the rectum; it caused profuse sweating and diuresis.

I have known many people with food allergies (or with lingering cold or flu symptoms) who said that although their abdomens were distended and uncomfortable, they were so thoroughly constipated that no laxatives worked. When their bowels did move, they sometimes described ribbon-shaped feces. Occasionally I saw their X-rays, in which an opaque "meal" showed up as a very thin and intermittent filament. It appeared that the wall of the bowel was enormously swollen. One woman complained that enemas were useless, because when a quart of water was injected, nothing returned from the bowel, though she would have to urinate more than usual. The colon was obviously drinking the water. I suggested that she try a hypertonic glucose and salt enema, with an aspirin added, neutralized by a little soda, and she immediately had good results.

People with less complete obstruction can get the same effect by drinking a hypertonic solution of epsom salts and sodium chloride, with an aspirin. Although this osmotic deflation of inflamed tissue is crude, I think it helps to promote real recovery, by reducing the reactivity of the tissue, and allowing it to recover its normal energy patterns.

In PMS, edema is a common problem, and it used to be thought that edema of the brain was responsible for the irritability or depression or other nervous symptoms, and diuretics such as ammonium compounds and urea were commonly used. (Premenstrual salt cravings are the result of the estrogen-disturbed water balance, and salt-restriction for PMS is as inappropriate as it is for pre-eclampsia or toxemia of pregnancy.) Alkaloids are often active in modifying the water content of physical systems, as well as of cells. The alkaloids that are often used in treating PMS seem to favor improved oxygenation and elimination of edema. I suspect that these drugs, and the natural hormones progesterone and pregnenolone, act in the same direction as hyperosmolarity.

For several years, I have been interested in the biological effects of ammonia, and compounds that are metabolically close to it. There is

clear evidence of ammonia's antiviral effect, which stimulated extensive research by drug companies seeking patentable antiviral amines. Most simple substances have regulatory functions in themselves, besides participating in other systems. Besides viral immunity, I think ammonia is involved in regeneration and nerve modulation. Urea, inosine, GABA, the polyamines, and betaine derivatives (e.g., gamma-butyrobetaine) are closely related to ammonia metabolism, and combinations of them will probably have many useful biological effects.

Sodium chloride, glucose, and other substances can be used at high concentrations for their osmotic effects, but they also have chemical and metabolic effects that aren't necessarily desirable. Both osmotic and biochemical effects should be taken into account in a given therapy.

Solving Some of the Problems of Aging

Townsend Letter for Doctors, January, 1991

In the 1970's a strange "Pine-sol" type disinfectant with insecticide was widely promoted in Mexico, and nearly every bathroom, bus, and public room in the country smelled of that rank, un-pinelike substance. One morning I woke around 3 AM smelling Pinosol, and as I was trying to decide where the smell was coming from, I realized that I could smell it only while exhaling—it was coming from inside me. From then on, I began to wake up every night, usually between 2 and 4 AM. I knew that many old people like to get up and start their day a little before dawn, but after this experience I began to notice that many younger people have—and are disturbed by—a similar alteration of their sleep rhythm.

Around the time of my Pinosol experience (in 1979) I happened to find a dead bug in my Nescafe bottle, and it occurred to me that this was the first bug of any kind that I had seen since I arrived in Jalapa. Walking to the outskirts of the town, where there were forests, I found a reasonable number of insects, but I couldn't find one in the city. This fact, combined with my awareness that my tissues were soaked with insecticide, (and other discomforts) caused me to quit my job at the university and return to Oregon. As I was driving across the desert, I noticed that I would smell Pinosol whenever it was meal-time. Apparently low blood sugar, causing fat mobilization, would cause the insecticide to be released into my blood. I had been back in Oregon for several weeks before I quit smelling it at meal-times and in the middle of the night. But even when I couldn't smell the chemical I kept waking around 3 AM, and I got in the habit of drinking milk or orange juice to raise my blood sugar enough to lower my adrenalin (and cortisol) so that I could return to sleep.

Since I had already spent years investigating the effects of light on hormones and health, I began to see that the existing knowledge regarding the involvement of stress and glucocorticoid hormones in the aging process meshed perfectly with my concept of "winter-sickness" and the role of inadequate light in the stress-related diseases such as the premenstrual syndrome, colitis, osteoporosis, and depression.

Besides looking for the precise ways in which light acts on us (such as by preserving the function of the essential respiratory enzyme, cy-

tochrome c), I also considered the dietary factors which might exacerbate the problem of light deficiency (such as an excess of unsaturated fats) and the possibility of other therapies, including drugs, that might be more practical and economical than hormone supplementation.

When various kinds of cells are deprived of energy (mast cells are often studied) they tend to produce (and secrete) histamine (among other substances). Unsaturated fats promote the release of histamine, while short-chain saturated fats, and glucose, inhibit it. When mice are killed by a variety of methods, they are found to have very high tissue histamine levels, so the high-histamine phenomenon seems to be about as generalized as shock. People who suffer from nocturnal asthma are known to have their highest blood level of histamine around 4 AM. Some inhibitory cells in the brain (including those involved in the "coma" state of protective inhibition) secrete acetylcholine. The similarity of the effects of histamine and acetylcholine are such that many people used to think of histamine as the "systemic cholinergic" hormone equivalent to acetylcholine. As a result of their similarity, any chemical which interferes with one of these "transmitter substances" is likely to interfere with the other, though not necessarily in the same way.

People who are awake in the dark have higher levels of cortisol than when they are asleep in the dark, that is, sleep is a partial defense against the stress of darkness. The cortisol (an adrenalin) secreted in darkness, or other stress, has the important function of maintaining the blood sugar level. The fact that cortisol causes the destruction of tissue to convert to glucose is the reason that stress and hypoglycemia are destructive. In 1971 I found that none of the sexually mature hamsters in our lab had any detectable thymus glands during the winter, though they all had them in the summer. Since estrogen and testosterone, the other thymus-shrinking hormones, are lower in the winter, I inferred that it was cortisone which caused their loss of thymus in the winter.

The main inhibitory "transmitter" substance in the brain is GABA (gamma amino butyric acid), which is closely related to aspartic and succinic acids. GABA has many anti-stress effects, besides the direct brain-quieting action. For example, it causes a sequestration of insulin, keeping some sugar from being turned into fat, and it promotes progesterone formation, which protects many systems from damaging hyperactivity.

Succinic acid was found by Szent-Györgyi to stimulate tissue respiration. Others found that it promotes the production of protective steroids, and more recently it was found to be the best material for chelating and removing aluminum from mitochondria. Succinic acid was identified as a major component of Vladimir Filatov's biogenic stimulators of tissue regeneration. Finding food sources rich in this material (especially in combination with the closely related butyric acid) would be desirable.

I experimented with various herbs known to have antihistamine and anticholinergic action, with the thought that they would help to sustain blood sugar through the night. (For example, insulin secretion is stimulated by acetylcholine from cholinergic nerves, and lowering its action during the night would decrease the need for adrenalin and cortisol.) My best results so far have been with a combination of the mildly sedative Jimson weed and the stimulant Ephedra; in combination, it seems that their antihistamine and glucose sustaining effects predominate, allowing comfortable sleep without the dry-mouth effect of their anticholinergic action.

It is now clear that both stress and an excess of the glucocorticoid hormones cause brain damage (as well as damage to all other organs). Marion Diamond's work with rats (confined or free) showed that stress causes very general brain damage, including to the cortex, and others have shown specific damage to the hypothalamus, the hippocampus, and other brain areas.[1] (Nerve cells are replaced by connective tissue cells. I think the damage is analogous to the viral (or "prionic") disease, scrapie; brain tissue from a scrapie infected young animal is antigenically similar to tissue from an old animal without the infection.)

Excessive cholinergic action in itself can cause brain damage.[2] The anticholinergic drugs, amantadine (Symmetrel) and atropine (related to the substances in Jimson weed) have been used to treat Parkinson's diseases. Atropine used to be listed as antidote for many poisons, probably because of its stabilizing effect on the nerves. It also promotes the formation of the protective hormone progesterone. Efficient energy production keeps the body from moving either to the "cholinergic" extreme or to the glucocorticoid extreme. When the mitochondria are damaged, the protective steroid pregnenolone (which is made in the mitochondria from cholesterol) can't be produced. In young people, the brain contains a very high concentration of pregnenolone and its derivatives, DHEA and progesterone, all of which stabilize cells and

protect against the effects of cortisol, but in old age these fall to about 5 % of their normal concentration, leaving the brain exposed to the destructive action of cortisol. The protective hormones can be used directly, or their synthesis can be promoted by using succinic acid, thyroid, vitamin A, and the atropine-type drugs, and maintaining adequate cholesterol. (T. Shimamoto, et al. have reported that low cholesterol is associated with a high incidence of stroke, especially hemorrhagic stroke.)

Since excessive excitation of cells (relative to the energy that's available) causes cells to die (in the brain, as elsewhere), it is important to consider as many of the natural means of inhibition as possible, while doing everything possible to sustain energy production. Succinic acid and butyric acid seem to be involved in both the energy sparing and the energy producing processes. The amino acids taurine and glycine are also considered to be inhibitory transmitters in the brain. Gelatin, which is extremely rich in glycine, is often added to fruit juice to take at bedtime as a sleep-supporting drink. Several of the local anesthetics including procaine and lidocaine, have cell-protecting action. Their anti-inflammatory or antihistamine function is probably caused by a more general cell-stabilizing effect. For example, lidocaine is used to prevent heart arrhythmia, and it can prevent tired heart cells from taking up too much calcium (which depletes cellular energy, in a deadly vicious circle). When taken orally at bedtime they act directly on the intestine (especially if there is inflammation anywhere in the intestine) to normalize its function, and even an occasional dose can have a long-lasting effect on the general health.

Estrogen, too, causes brain damage. Its prenatal effect on the brain has been known for many years. Marian Diamond found that estrogen, like the stress of confinement, causes the cortex and other parts of the brain to be smaller than normal; she also found that progesterone, opposing estrogen, enlarges the cortex.

It has been suggested that estrogen's nerve-damaging action is caused by way of elevated glucocorticoid hormones. (In the "hamster lab" where I worked, other people showed that estrogen causes enlargement and hyperactivity of the adrenal cortex.)

When I first suggested that "aging is estrogenic," or that estrogen promotes aging changes, it was because of a large number of biochemical similarities in aging and in the state of estrogen dominance, and the absence of any detectable biochemical differences between the states,

except their history.[3] For example, in both states the oxygen tension is relatively low, and as a result, unsaturated lipids are rapidly changed into "age pigment" or lipofuscin through lipid peroxidation.

Insomnia and hot flushes commonly occur around the time of menopause. These and other symptoms of menopause can be produced by an excess of cortisol, as in Cushing's syndrome.[4] The increase of cortisol during the night is probably responsible for "night sweats." When progesterone is deficient, cortisol—even in "normal" amounts—has a stronger effect.

The animal evidence is now clear, showing that it is largely the prolonged exposure to estrogen which causes reproductive aging.[5] Treatment with progesterone can prolong fertility,[3,6] as well as controlling symptoms such as insomnia and osteoporosis.

Until we know how to modify the environment (especially the radiant spectrum in the region of 600 nm to 1200 nm) to minimize the stress of winter and nighttime, the use of nutrition and hormone balancing techniques can control symptoms and minimize the cumulative damage that is occurring while we have the symptoms.

Some Effects of Progesterone in Men

Ray Peat's Newsletter, 2021

CLASSIFYING progesterone as a "pregnancy hormone" and a "female sex hormone" has seriously limited understanding of its function in both men and women. It is a stabilizer of cellular structure and function in all organs, similarly in men and women. This stabilizing effect is especially important in the nervous system, where it is protective against stress. In both men and women, a progesterone deficiency is associated with problems including seizures and bipolar disorder, irritability/elation, aggression, and depression, as well as sex-related problems.

In the 1970s, an acquaintance told me that he had become impotent following his vasectomy. I was familiar with the progesterone deficiency produced in women by tubal ligation and by intrauterine contraceptive devices, and I had seen a study of men's hormones following a vasectomy, in which an isolated deficiency of progesterone sometimes occurred, so he decided to try some progesterone. He later said that a single dose had corrected his erectile problem. Other young men with erectile dysfunction, from other causes, had similarly good results with small amounts of progesterone.

When a problem is quickly and permanently corrected with a small amount of progesterone it seems likely that the progesterone acted in the brain to shift the balance, maintained by endorphins, away from the stress induced inhibition of progesterone and testosterone synthesis. At the same time, though, that progesterone is lowering cortisol, it is also reducing inflammation, partly by acting as an antagonist to aldosterone. Increased aldosterone is associated with erectile dysfunction,[1–3] and it interacts locally as a testosterone antagonist. In this, and other situations involving testosterone antagonists (estrogen, cortisol, aldosterone), progesterone can have a directly testosterone-supporting effect.

After the age of 35 or 40, many men experience a decline in their resistance to stress, corresponding to the decline in protective substances such as DHEA and progesterone. Often a small amount of progesterone, 5 or 6 mg (for example, a drop of Progest-E the size of an unpopped kernel of popcorn) can make a difference, sometimes lasting for a few days or more. Paying close attention, the effects are usually noticeable within

about half an hour. At a certain level, progesterone can antagonize the effects of testosterone; in younger men, 2 or 3 drops can have that effect. That effect passes within a day of stopping the progesterone. If a younger man uses progesterone topically, for example for sunburn, a little olive oil should be applied to the skin first to make it spread easily; if it's used on a large area, the same anti-testosterone effect is likely to be noticed.

Steroids/Thyroid

Blake College Newsletter, Volume 1, Number 4, 19XX

Steroids

THIS type of molecule might be the most common carbon compound in the universe. It is made by single celled organisms, by plants, and by animals, and has many kinds of function. The steroid hormones are involved in all aspects of animal physiology, and overlap with control functions of the nervous system, peptide hormones, metabolites, prostaglandins, cyclic nucleotides, etc. Sometimes people speak of "steroids" when they mean glucocorticoids such as cortisol or a synthetic like dexamethasone, or, among athletes, when they mean anabolic steroids or synthetic androgens; and so it is common to associate "steroids" with harmful side effects. All foods contain steroids and sterols (a major type, containing an alcohol group and a side-chain), some of which are beneficial and some of which are toxic or allergenic.

In animals, cholesterol is the basic sterol molecule, which is massively converted into other substances, including the steroid hormones. Thyroid hormone and vitamin A are required for this conversion. The first step occurs in the energy-producing mitochondrion, where cholesterol loses its side-chain and is slightly oxidized, producing pregnenolone. Being less fat soluble than cholesterol, pregnenolone leaves the mitochondrion, so it can't inhibit its own synthesis. Rather, it seems to stimulate its own synthesis, though this isn't as clearly established as in the case of progesterone.

Depending on the tissue, pregnenolone will be converted by enzymes in the cytoplasm into either progesterone or DHEA (also called DHA, dehydroepiandrosterone). The fact that progesterone (and probably pregnenolone) stimulates its own synthesis means that taking it does not suppress the body's ability to synthesize it, as happens with cortisol. Sometimes, one dose or a few doses can restore the body's ability to produce enough of its own.

Progesterone also allows the thyroid gland to secrete its hormones, especially when the thyroid function has been inhibited by estrogen. Since the thyroid hormone is needed to produce progesterone, a sup-

plement of either tends to normalize both thyroid and progesterone production.

Progesterone and DHEA are the precursors for the other more specialized steroid hormones, including cortisol, aldosterone (sodium-retaining hormone), estrogen, and testosterone. The formation of these other hormones is tightly regulated, so that taking the precursor will correct a deficiency of a specialized hormone, but will not create an excess. At least in the case of progesterone, an excess tends to balance or neutralize an excess of the specialized hormone, so it has been described as having anti-androgenic, anti-estrogen, anti-aldosterone, and anti-cortisol functions.

Many steroids have a protective ("catatoxic") action against a wide variety of poisons. Some of the quick effects (e.g., within 10 min) of progesterone and pregnenolone probably represent a catatoxic action, as well as a neutralizing or balancing of excessive estrogen or cortisol. Improved metabolic efficiency, sparing oxygen and glucose, will have a quick effect in reducing edema.

During pregnancy, very large amounts of progesterone are made. It protects and stabilizes practically all functions of both the mother and the fetus. Progesterone, glucose and the thyroid hormones powerfully influence the brain development and intelligence of the baby, probably by influencing both the number and the size of brain cells, and the quality of their functioning.

Part of progesterone's protective effect is a result of its quieting effect on cells. For example, it tends to prevent seizure activity in brain cells. During childbirth, its normal function is to act as an anesthetic. When the level of estrogen is too high, progesterone can't achieve this effect. In a non-pregnant person, it is important to determine the minimum effective dose by taking only a few drops at a time, and repeating this small dose about every 20 min until symptoms have been controlled. Otherwise, serious "drunkenness" can be produced, with loss of coordination, and even unconsciousness.

The only solvent for progesterone which isn't toxic and which will dissolve an effective quantity, is vitamin E. In this form, it can be absorbed through the skin or other membranes, or can be taken orally. Taken orally, it is absorbed as chylomicrons, going into the general circulation (as vitamin E does), instead of to the liver where it would be prepared for excretion. In this form, therefore, it is fully and quickly available

to all tissues. It is approximately 20 times more powerful in its action than other preparations, so it is important to use it in physiological quantities, rather than in the huge doses commonly given rectally or by injection. 10 or 20 mg is often an effective dose, though people with low thyroid or high estrogen sometimes use 50 mg/day to 100 mg/day. In the customary 10 % solution, one drop contains about 3 mg progesterone, and 1 mL (1/4 tsp) contains 100 mg The first dose should never be more than 15 mg (An ounce of 10 % progesterone in vitamin E is $15; a dozen one-ounce bottles is $144.)

Pregnenolone, taken orally, does nothing noticeable to a healthy animal or person, but if the stress-related hormones are elevated, they return to normal when pregnenolone is taken. The brain contains much more pregnenolone, DHEA, and progesterone than do other organs or the blood, and these levels decrease progressively with age. Older people are more likely to feel an effect from pregnenolone, than are young people. (A 10 g bottle of pregnenolone is $20; 0.25 kg is $250. 0.1 g is a reasonable first dose, though some people seem to need as much as 1 g/day.)

Thyroid

Measuring the amount of thyroid in the blood isn't a good way to evaluate adequacy of thyroid function, since the response of tissues to the hormone can be suppressed (for example, by unsaturated fats).

In the 1930's accurate diagnosis was made by evaluating a variety of indications, including basal oxygen consumption, serum cholesterol level, pulse rate, temperature, carotenemia, bowel function, and quality of hair and skin. A good estimate can be made using only the temperature and pulse rate.

Oral or armpit temperature, in the morning before getting out of bed, should be around 98 °F, and it should rise to 98.6 °F by mid-morning. This is not valid if you sleep under an electric blanket, or if the weather is hot and humid. A person who is hypothyroid produces heat at a low rate, but doesn't lose it at the normal rate, since there is less sweating, and the skin is relatively cool. Many hypothyroid people compensate with high adrenalin production (sometimes 40 times higher than normal), and this tends to keep the skin cool, especially on the hands, feet, and nose. The high adrenalin is the consequence of low blood glucose, so a

feeding of carbohydrate, such as a glass of orange juice, will sometimes lower the pulse rate momentarily. Healthy populations have an average resting pulse rate of about 85/min. Especially in hot weather it is useful to consider both temperature and pulse rate.

The Achilles tendon reflex is another quick way to estimate thyroid function. This reflex is used because of the insignificant weight of the toes in relation to contraction of the gastrocnemius muscle. The T (repolarization) wave on the electrocardiogram is a similar indicator of the rate of energy production. Thumping the Achilles tendon causes the muscle to contract (unless it is already in a semi-contracted state, which isn't uncommon). The contraction consumes energy, and the muscle can't relax until enough energy has been produced to restore the threshold and the readiness for a new contraction.

If energy production is efficient, relaxation is faster than the passive return motion of the foot, so the foot swings freely back to its original position, and over shoots slightly, causing a slight swinging action. In hypothyroidism, the foot returns as if controlled by a pneumatic door-closer, and settles slowly and precisely into its relaxed position, sometimes with a hesitating, intermittent motion. This slow replenishment of energy, and slow relaxation, can cause muscles to cramp easily. The aching leg muscles of children at the end of an active day are often a sign of hypothyroidism, and sometimes the gastrocnemius muscle becomes very swollen and hypertrophied in hypothyroid children. The same process, of slow energy regeneration, can cause rhythm disturbance in the heart, and often causes insomnia and restless sleep.

The thyroid gland secretes about 3 parts of thyroxin to one part of triiodothyronine, and this allows the liver to regulate thyroid function, by converting more of the T_4 to the active T_3 when there is an abundance of energy. Glucose is essential for the conversion, so during fasting there is a sharp decrease in metabolic rate, and in experiments, 200 or 300 calories of carbohydrates can be added to the diet without causing fat storage.

When the liver is the main cause of hypothyroidism, your temperature (and especially the temperature of your nose, hands and feet) will fall when you are hungry, and will rise when you eat carbohydrates. If a hypothyroid person has a very slow pulse, and feels lethargic, it seems that there is little adrenalin; in this case, a feeding of carbohydrate is

likely to increase both the pulse rate and the temperature, as the liver is permitted to form the active T_3 hormone.

Women often have above-average thyroxin, with symptoms of hypothyroidism. This is apparently because it isn't being converted to the active form (T_3). Before using a Cytomel (T_3) supplement, it might be possible to solve the problem with diet alone. A piece of fruit or a glass of juice or milk between meals, and adequate animal protein (or potato protein) in the diet is sometimes enough to allow the liver to produce the hormone. If Cytomel is used, it is efficient to approximate the physiological rate of T_3 formation, by nibbling one (10 or 25 μg) tablet during the day. When a large amount is taken at one time, the liver is likely to convert much of it to the inactive reverse-T_3 form, in a normal defensive response.

Women normally have less active livers than men do. Estrogen can have a directly toxic effect on the liver, but the normal reason for the difference is probably that temperature and thyroid function strongly influence the liver, and are generally lower in women than in men. Estrogen inhibits the secretion of hormone by the thyroid gland itself, probably by inhibiting the proteolytic enzyme which dissolves the colloid. Progesterone has the opposite effect, promoting the release of the hormones from the gland. At puberty, in pregnancy, and at menopause, the thyroid gland often enlarges, probably as a result of estrogen dominance.

Thyroid function stimulates the liver to inactivate estrogen for secretion, so estrogen dominance can create a vicious circle, in which excess estrogen (or deficient progesterone) blocks thyroid secretion, causing the liver to allow estrogen to accumulate to even higher levels. Progesterone (even one dose, in some causes) can break the cycle. However, if the gland is very big, the person can experience a few months of hyperthyroidism, as the gland returns to normal. It is better to allow the enlarged gland to shrink more slowly by using a thyroid supplement. If an enlarged gland does begin to secrete too much thyroid hormone, it can be controlled with tablets of propylthiouracil, or even with raw cabbage or cabbage juice, and cysteine-rich meats, including liver.

Besides fasting, or chronic protein deficiency, the common causes of hypothyroidism are excessive stress or "aerobic" (i.e., anaerobic) exercise, and diets containing beans, lentils, nuts, unsaturated fats (including carotene), and undercooked broccoli, cauliflower, cabbage, or mustard greens. Many health conscious people become hypothyroid with

a synergistic program of undercooked vegetables, legumes instead of animal proteins, oils instead of butter, carotene instead of vitamin A, and breathless exercise instead of a stimulating life.

Stress and Water

Healing Village E-Zine, August, 2015

THE biological idea of stress refers to the difficulty of adapting, and this involves energy, structure, and insight/orientation. Given enough energy, we can often adjust our structure to achieve full adaptation, and with insight, we can minimize the amount of energy and structural change needed, for example just by a change of pace or rhythm.

Change of structure can involve the growth of new cells, or the enlargement or modification of existing cells, and the shrinking or dissolution (apoptosis) of existing cells, allowing their substance to be used elsewhere. F. Z. Meerson's work gave a clear framework for understanding this, especially in relation to the adapting heart, and Eli Mechnikov's picture of the creative role of the phagocyte in growth can be seen as one of the most basic insights into biology.

A given structure makes possible a certain level of useful energy, and adequate energy makes possible the maintenance of structure, and the advance to a higher and more efficient structural level.

I have been using aging (menopause and the ovaries) and cancer (carbon monoxide as a hormone of "cellular immortality") to explore the issue of cell renewal and tissue regeneration. Yesterday, Lita Lee sent me an article about K. P. Buteyko, describing his approach to the role of carbon dioxide in physiology and medicine. Buteyko devoted his career to showing that sufficient carbon dioxide is important in preventing an exaggerated and maladaptive stress response. He advocated training in "intentional regulation of respiration" (avoiding habitual hyperventilation) to improve oxygenation of the tissues by retaining carbon dioxide. He showed that a deficiency of carbon dioxide (such as can be produced by hyperventilation, or by the presence of lactic acid in the blood) decreases cellular energy (as ATP and creatine phosphate) and interferes with the synthesis of proteins (including antibodies) and other cellular materials.

When I first heard of Buteyko's ideas, I saw the systemic importance of carbon dioxide, but I wasn't much impressed by his idea of intentionally breathing less. If the hyperventilation is produced by anxiety, then a deliberate focussing on respiration can help to quiet the nerves.

Knowing that hyperventilation can make a person faint, because loss of carbon dioxide causes blood vessels in the brain to constrict, I saw that additional carbon dioxide would increase circulation to the brain. This seemed like a neat system for directing the blood supply to the part of the brain that was more active, since that would be the part producing the most carbon dioxide.

In a nutrition class, in the late 70s, I described the way metabolically produced carbon dioxide opens blood vessels in the brain, and mentioned that carbonated water, or "soda water," should improve circulation to the brain when the brain's production of carbon dioxide wasn't adequate. A week later, a student said she had gone home that night and (interpreting soda water as bicarbonate of soda in water) given her stroke-paralyzed mother a glass of water with a spoonful of baking soda in it. Her mother had been hemiplegic for 6 months following a stroke, but 15 minutes after drinking the bicarbonate, the paralysis lifted, and she remained normal.

Later, a man who had stroke-like symptoms when he drank alcohol late at night, found that drinking a glass of carbonated water caused the symptoms to stop within a few minutes.

Realizing that low thyroid people produce little carbon dioxide, it seemed to me that there might be a point at which the circulatory shut-down of unstimulated parts of the brain would become self-sustaining, with less circulation to an area decreasing the CO_2 produced in that area, which would cause further vasoconstriction. Carbon dioxide (breathing in a bag, or drinking carbonated water, or bathing in water with baking soda) followed by thyroid supplementation, would be the appropriate therapy for this type of functional ischemia of the brain.

When there is circulatory stasis, the tendency of the blood to clot is increased. Normally, the legs are where small clots form most often, but the same thing is likely to happen in the brain when circulation is too slow. Carbon monoxide poisoning mimics multiple sclerosis by causing clots to form in the brain, in association with areas of demyelination. Physiologically, I think hypothyroidism, combined with high estrogen (which promotes blood clotting) is the main cause of MS, possibly overlapping with a variety of other demyelinating factors, such as tin, hexachlorophene, heme, and a deficiency of progesterone. One of estrogen's effects is to cause edema, probably because it blocks albumin

synthesis, and the loss of blood volume associated with edema increases the tendency to clot.

People have examined the behavior of carbon dioxide dissolved in water when the water is in contact with the skin, as during a bath in carbonated water. Since the concentration of metabolic carbon dioxide in the living tissue was higher than the concentration in the water, it was assumed that CO_2 would move from the tissue into the water, "down its gradient." But the opposite happened, the carbon dioxide moved from the water into the tissue, against the gradient. This shows that we can draw false conclusions when we think of the body as a "watery system." The carbon dioxide is more soluble in living tissue than in ordinary water, and solubility is what governs the situation, not a context-free concentration gradient. Many natural springs that have a reputation for healing contain carbon dioxide and carbonates, which the body absorbs when bathing in or drinking the water.

Carbon dioxide is more soluble in oil than in water. In general, gases dissolve better in cold water than in warm water, and cold water has more affinity for fats than hot water does. In many ways, the water in cells acts as though it were colder than it is, and more oil-loving. The term "structural temperature" is used to describe the behavior of cellular water which, at body temperature, behaves like ordinary water at a lower temperature–it has a "lower structural temperature." There is a reciprocal action between the cell water and the material it dissolves, so that carbon dioxide tends to stabilize the normal high energy state of the cell. I will say more about cell water after saying a little more about Buteyko's focus on carbon dioxide.

Although it is easy to dismiss Buteyko's emphasis on the "Intentional Cessation of Deep Respiration" as a therapy, his work on the importance of carbon dioxide is sound. When I realized that many hypothyroid people compensate by producing huge amounts of adrenaline, which helps to sustain their blood sugar and their nervous energy, and that adrenaline tends to cause hyperventilation, I saw that "intentional regulation of respiration" might work in these people to reduce hyperventilation just as psychotherapy, reassurance, meditation, or taking a nap can help to control hyperventilation and other effects of excess adrenaline and anxiety. But using carbon dioxide, or a thyroid supplement to promote the body's formation of carbon dioxide, seems like a more logical approach to treatment of a carbon dioxide deficiency.

I have been concerned about the probable effects on the fetus of the silly panting respiration that is being taught to so many pregnant women, to use during labor. Panting blows out so much carbon dioxide that it causes vasoconstriction. Possibly the uterus is protected against this, and possibly the fetus produces enough carbon dioxide that it is protected, but this isn't known. Especially if the mother is hypothyroid, it seems that this could interfere with the delivery of oxygen to the fetus. Besides vasoconstriction, Buteyko points out that the Bohr effect, in which CO_2 causes hemoglobin to release oxygen, means that a low level of carbon dioxide decreases the availability of oxygen. If the Bohr effect applies to fetal hemoglobin, then this suggests that the mother's panting will deprive the fetal tissues of oxygen.

It is normal for the fetus to be exposed to a high concentration of carbon dioxide. Recent experiments with week-old rats show that carbon dioxide, at the very high concentration of 6 % powerfully protects against the brain damage caused by oxygen deprivation (tying a carotid artery and administering 8 % oxygen).[1]

I have talked to several people who get mild neurological symptoms around 2 to 4 AM, and since the symptoms are like those caused by hyperventilation, I think nocturnal low blood sugar and high adrenaline might produce relative hyperventilation and poor oxygenation, possibly with lactic acidemia. A sizable part of the population responds to intravenous lactic acid with a panic attack, and I think these people are hypothyroid ; if glycogen stores are low, lactic acid exacerbates the energy problem, and by displacing carbon dioxide could trigger hyperventilation. When a panic attack is induced by stress, it is probably because the stress is causing the production of lactic acid. Both sugar and carbon dioxide help to prevent panic attacks, according to some recent studies.[2,3]

Buteyko has made an unusual observation, which I think is important. He says that the oxygen deprivation resulting from a deficiency of carbon dioxide can cause increased arterial pressure, and also a dilation of veins, leading to varicose veins and hemorrhoids. (I discussed this behavior of the blood vessels in "A Unifying Principle.") In a lecture, Buteyko argued that a deficiency of carbon dioxide causes allergies, sclerosis, psychosis, tuberculosis, precancerous conditions, and other symptoms.

His list of diseases is reminiscent of Broda Barnes' work, in which he showed that tuberculosis, cancer, and atherosclerotic heart disease are endemic in hypothyroid regions.

This is where the issue of cell water comes in. Carbon dioxide, produced by oxidative cell metabolism, is associated with the high energy state of the cell. When something interferes with oxidative metabolism, lactic acid is produced instead of carbon dioxide. If the cell stays very long in this low oxygen state, it swells, taking up water. (The fatigued muscle, for example, can take up so much water in a short time that it weighs 20 % more than before it began working so intensely that its energy needs far exceeded the availability of oxygen. This swelling is what causes the soreness and tightness of intense exercise. The swelling persists long after the liver has cleared the lactic acid from the blood.)

This swelling from taking up water is involved in one type of "edema," and in inflammation, or activation of the cells by hormones, as well as by simple oxygen deprivation. When the eyes have been closed for several hours, the cornea swells, because it depends on direct contact with the air for its oxygen, and the eyelid, whose circulation provides oxygen for its own cells, doesn't provide enough for the cornea.

Estrogen seems to work by blocking oxidative metabolism, and its first visible effect is to cause the stimulated tissue to take up water.

Anything that causes cells to take up water seems to stimulate cell division. For example, just putting cells in a hypotonic medium stimulates cell division (and a hyperosmotic environment stops cell division).

Years ago I noticed that various enzymes which are activated by estrogen are completely inactivated by cold, and I proposed that estrogen's effect was to raise the "structural temperature" of cell water. If estrogen-stimulated cells have a "high structural temperature," their ability to dissolve oxygen will be reduced. (Whatever the mechanism, estrogen does shift cells away from oxidative metabolism. I think many mechanisms are involved.)

Thyroid, which opposes estrogen's effects on cell energy, stimulates oxidative metabolism with the production of carbon dioxide, and reduces the water content of tissues.

Buteyko suggested that carbon dioxide directly supports immunity. Increasing the availability of oxygen and the production of ATP should be good for immunity, apart from any more specific effects. If it contributes to an effect on the "structural temperature" of cell water, and helps

to raise the energy charge of the cell, CO_2 could be a major factor in opposing the action of estrogen. While the general effects of thyroid can be easily observed, many of its ways of achieving those effects are still not known.

Typical cancer cells are much wetter than normal cells, containing 90 % or 92 % water. It is possible that part of thyroid's anti-cancer, immune promoting effect is the result of the increased carbon dioxide it produces. Since lactic acid turns out to have a variety of "signalling" functions, including effects on white blood cells, it seems possible that carbon dioxide has a different set of signalling or hormone-like functions.

While I doubt that lactic acid produces intracellular acidosis (ATP hydrolysis produces acidosis[4,5]), it can produce temporary extracellular acidosis, besides any specific hormone-like action. This acidosis could be involved in autoimmune processes, since it can change cells' immunological reactivity.[6]

It is very likely that cancer patients lack carbon dioxide, because tumors produce significant amounts of lactic acid, which tends to displace carbon dioxide. It would be interesting to see whether supplemented carbon dioxide would decrease the cancer's production of lactic acid.

Short-chain fats are very soluble, and are quickly metabolized, so it is likely that coconut oil, which is rich in short and medium-chain fatty acids, will tend to decrease the production of lactic acid.

High pressure tends to act as a cell excitant (e.g., it can cause a muscle to contract), and in effect is raising the "structural temperature" of cell water. This suggests that the reduced pressure of high altitude would have the beneficial (antistress) effect of decreasing the structural temperature of cell water. This means that gases would have a higher solubility in cell water at high altitudes, which would tend to slightly offset the biological effect of the relative scarcity of air at high altitude. There is some evidence[7] that reduced pressure increases the solubility of oxygen in cells. The presence of carbon dioxide should increase this effect. (Drost-Hansen discusses some examples of "anomalous" concentration effects of hydrocarbon/water mixtures in "Anomalous Temperature and Pressure Dependencies of Gas Solubilities: Laboratory and Field Observations."[8, p. 254]) I think Drost-Hansen's reasoning suggests that the short-chain fatty acids might also increase the solubility of oxygen in cell water. If this is true, it suggests that coconut oil might

have a very important antistress effect, sustaining efficient respiration during demanding situations.

Some of the other implications of thinking about the special nature of cell water are discussed in the works of Cope[9] and Ling.[10]

Supplement Safety

Townsend Letter for Doctors, May, 1990

AROUND 1976, there were some warnings about the occurrence of kidney and breast cancers from prolonged use of reserpine, which had been very popular for controlling blood pressure. It was thought that the elevation of prolactin by reserpine accounted for the production of tumors. Since tryptophan stimulates prolactin secretions, I thought it might turn out to be just as carcinogenic as reserpine. The people who sell tryptophan don't want to hear this.

Olney's work in the 1970's with aspartic and glutamic acid should have aroused the public to be cautious about the use of isolated amino acids. Even after these amino acids were shown to cause seizures, many companies continued to sell them without warnings.

Orotic acid was known to alter pyrimidine and ammonia metabolism, so I thought it wasn't wise to use supplements that contained large amounts of it. A couple of years ago orotic acid was described as "an excellent liver carcinogen," based on experiments with rats. I have known people who used it regularly in quantities similar to those which are carcinogenic for rats. But it continues to be sold, without warnings.

In 1953, a few small tablets of ascorbic acid completely cured my poison oak and I never got it again though I worked in the woods every summer for several years. But in the late 1950s, I had cold-like symptoms for a few days after I took a 500 mg tablet, and the same thing happened when I took another tablet a few months later. In the late 1960s, I began taking ascorbic acid regularly and I had a chronic cough; about a year later, I developed bleeding colitis. These symptoms stopped when I stopped taking ascorbic acid. I found that I could detect a very small amount of synthetic ascorbic acid in processed foods, by the recurrence of those symptoms. Over the years, seeing other people with similar symptoms, I would tell them about the allergenicity of vitamin tablets or powders, and their symptoms would go away. In this way I saw that the most frequent sensitivity was to ascorbic acid, riboflavin, and rutin. Later, I learned that these are synthesized from cornstarch. Synthetic ascorbic acid contains significant amounts of heavy metals, apparently introduced by the use of sulphuric acid as an oxidant. (The manufacture of sulphuric acid has customarily involved the use of a "lead room." I

don't know whether this technology is still in use.) I experimented with large daily intakes of vitamin C, for example 4000 mg per day in the form of fresh grapefruit juice, and didn't experience any unpleasant reaction, but 1 or 2 mg of the synthetic form—taken by accident in foods such as all-bran breakfast cereal, bread, or sausage, which I didn't suspect would contain added ascorbic acid—would cause days of sickness with intestinal bleeding. Since my reactions to metabisulfite and to synthetic ascorbic acid are similar, though not identical, I suspect that sulfur compounds produced in manufacturing ascorbic acid are partly responsible for its allergenicity.

Interestingly, I have had strong allergic reactions to several kinds of single amino acids; I suspect that these, and many other foods and supplements, are exposed to sulfites or ascorbic acid that have been used as preservatives at some stage of manufacture.

Although more people are writing about the dangers of iron supplementation now than when I wrote about it in *Nutrition for Women* in 1975, it seems that people are using just as much as ever. A hundred years ago, arsenic was the common treatment for "anemia," and it "worked," just as iron works to raise the production of red blood cells. This "anti-anemia" effect is a reaction to injury, and has nothing to do with a nutritional iron deficiency. Even heavy menstruation involves the loss of only 30 or 40 mg of iron per month, or about 1 mg per day, and it is practically impossible to get such a small amount in the diet. Immunosuppression and carcinogenesis by iron have been well established for about 20 years.

Substance Abuse

The Center for Science in the Public Interest got a lot of publicity a few years ago when it petitioned the FDA to require warning labels on products that contain caffeine. Many other groups circulate warnings about the "dangers" of coffee. When coffee was introduced into Europe, some people seemed to think it was an evil witch's brew; Bach's Coffee Cantata ridiculed the great fear of coffee.

To make false claims about anything abuses the truth. A network of mistaken beliefs can lead to a perverted culture, which ignores important issues because of an obsession with false issues. I think it is useful now

and then to outline the kinds of mistakes that are being made regarding the abused substances, coffee and caffeine.

Dr. Minton at Ohio State, and the mass media which mindlessly echoed his beliefs, started a cultish idea that caffeine caused cystic breast disease. His publications are marvels of ignorance and irrationality, which probably someday will be used in college classes to illustrate America's blind faith in the cult of medicine. Other studies found an entire lack of association between caffeine and breast disease, but I will not be surprised if caffeine is ultimately found to be therapeutic for some types of cystic breast disease, because of its effects on hormones and cell-regulation.

Decaffeinated coffee was found to be associated with cancer of the pancreas. A residue of solvent in the coffee is a likely candidate for explaining the association, since the other groups found by epidemiologists to have a high rate of pancreatic cancer were people who work in gasoline stations and in dry-cleaning businesses. Several studies have found caffeine to have a protective effect against cancer. For example, Würzner, et al.[1] found that tumor incidence in rats fed coffee went down as the caffeine content went up.

Caffeine has several effects which protect against cancer. It strongly protects against the cancers caused by chemical carcinogens (including those in smoke), and even against those caused by ultraviolet radiation. It stimulates the repair process which corrects mutations (in mammals, but not in bacteria), and it stimulates the immune system.

I think some of the beneficial effects of caffeine result from its stimulation of the thyroid gland, and of normal respiration. While it stimulates normal respiration it has an anti-inflammatory action, which probably involves both prostaglandin regulation and an antioxidant action. It is chemically very similar to our natural antioxidant, uric acid, and it raises the level of uric acid in both the blood and the urine.

Giving rats the human equivalent dose of 3500 mg/day has no harmful effects, even when continued for several generations. One study found no harmful effects when rats were fed large amounts of caffeine for up to three and a half years. Since lab rats rarely live that long, I think caffeine's effects on longevity should be investigated.

Theophylline, found in tea, is very similar to caffeine. It has been shown experimentally to retard the growth of cancer cells, and even to promote their recovery of normal function. It is widely used to treat

asthma. Theophylline and caffeine have been used to treat apnea in infants, since they stimulate the nerves that regulate breathing. Many people who use theophylline for their asthma don't realize that a few cups of tea would provide the same drug, more pleasantly and less expensively.

Dietitians and their textbooks generally suffer from a cultish belief that coffee and tea "have absolutely no nutritional value." The British found that tea and coffee provide about 20 % of their national dietary intake of several essential nutrients. When the complete absence of certain essential nutrients in white bread was discussed, dietitians defended the use of white bread as an appropriate part of a balanced diet. I mention this simply to establish the cultish nature of their professional behavior, not to advocate the use of whole grains or a larger consumption of tea.

Szent-Györgyi's Energy

Townsend Letter for Doctors, August/September, 1989

A few years ago someone found that yellowing deciduous leaves in the fall were in the state of protein catabolism. I have discussed how this parallels the "toxic" effect of night and winter on animals; the darkness damages mitochondria, and red light seems to be the most effective frequency in restoring their function. The observation that cortisone begins to rise (in humans) when lights are turned out, rather than when people begin to sleep, nicely fits with the rabbit mitochondria studies, and the autumn leaves: either the cortisone causes the damage, or, more probably, the mitochondrial inefficiency wastes glucose, and increased adrenalin, cortisone—and dreaming—are responses to hypoglycemia.

At the moment I am working on the idea that potato plants, which do not normally produce seeds, can be induced to do so by blue (and other high frequency) light—at least when grown in acidic soil which provides iron or other heavy metals which tend to generate free radicals. This idea is a kind of generalization of the idea I first heard around 1953, from an old forester who knew that a coneless pine tree could be caused to produce a heavy crop of seed by injuring it with an ax. There are many other examples of the same process, such as grass which produces seed early when the weather is dry. The many toxic effects of estrogen caused me to interpret its effects (for example, rapid cell division in the uterus) as another example of the same process. In the 1940s, people often talked about famine causing extremely early fertility in girls; although it wasn't much discussed at that time, starvation (and other stress) does cause an elevation of estrogen.

Since Albert Szent-Györgyi died I have been thinking about his idea that the "Hopkins electron pool," stored in cellular proteins provides the energy for cell division. Around 1972, someone reported that sunlight shining on dark hair induces free radicals, and that these free radicals persist for hours in darkness. But exposure to red light "quenches" the free radicals within seconds.[†]

[†] Some people now consider melanin to be an anti-oxidant. It is important not to confuse melanin with lipofuscin, which is produced under oxidative stress and is able to accelerate the wastage of oxygen and energy.

My idea of the "toxicity" of darkness is that free radicals (produced by metabolism, or maybe by cosmic rays) accumulate with time, but that the red component of light normally quenches them. In darkness, the excess of excited electrons would begin to spread beyond their safe storage system, and to cause toxic effects, such as oxygen wastage.[†] Many toxins and stressors are known to act through a common pathway of free-radical damage;[‡] this accounts for the generalized protective effects of certain substances, such as vitamin E (as discussed by Meyerson in *Ray Peat's Newsletter* #29).

One of the most sensitive tests of estrogen's effect is the reduction of a dye (called TTC) by tissue and whole cells;[§] it is reduced (theoretically) by various "dehydrogenases." (The Hopkins electron pool was called by E. Racker "nothing dehydrogenase"). Progesterone blocks estrogen's effects on this dye. Since a similar dye has been used to measure the activity of superoxide dismutase (SOD), it seems that the superoxide radical can reduce the dye. Whatever the source of the electrons, estrogen and progesterone act in different directions on their availability. Progesterone is known to inhibit cell division in various situations: in the uterine endometrium, in cancer, and in frogs' eggs.

Several years ago, someone found that the progesterone in frogs' eggs was bound to the melanin—whose function in the eggs was never

[†] Oxygen wastage itself will block respiration, disrupt mitochondrial function, and allow intracellular calcium to increase. There is clear evidence that many types of cell damage lead to cell death by a common "calcium path." Tissue stress has many self-promoting loops: enzyme release, formation of carbon monoxide and probably cyanide, retention of iron, etc. Sulfur, especially as the sulfane and sulfhydryl forms, is involved in many protective processes: see *Ray Peat's Newsletter* #5, 6 and 50. Deposition of calcium and iron are closely associated, and in oxygen deficiency iron becomes a major source of free-radicals, as discussed in *Newsletter* #41.

[‡] This pathway, according to Meyerson, is closely linked with the calcium-cell-death pathway; supplemental magnesium and vitamin E closely interact in protecting against stress.

[§] Disruption of the cell destroys the ability to reduce the dye, suggesting that something more than ordinary enzymatic reduction is involved. At least, the phenomenon would involve an extreme sensitivity to concentration. This violates the basic assumption of conventional (and stupid) "test-tube biochemistry," namely, that reactions in the test-tube meaningfully reflect what occurs in the cell. Le Chatelier's principle "when a balanced system is disturbed, the equilibrium will shift in a way to restore the original condition," shows how complex enzymes can change activity upon dilution, but this is not generally thought to apply to the dehydrogenases.

understood. (Though Szent-Györgyi for many years emphasized that pigments often exist invisibly inside organisms, and probably have electronic-metabolic functions, rather than the decorative function usually associated with pigments). Melanin generally exists as a complex with proteins. If the energy for cell division is stored in proteins, and if progesterone is acting on the eggs to inhibit cell division, and is bound to the melanin—which is known to store electronic excitation—then maybe progesterone is acting to prevent the escape of energy from the protein-melanin system.[†] If it does this generally, that could explain its very general "catatoxic" effects.

It was around 1954 that I first found some potato fruits, and hoped to get viable seeds with which to grow new strains of potato.[‡] Around that time, John Ott found that squash plants he was photographing with pink artificial light produced only male flowers. The next season he used bluish artificial lights, and his plant produced only female flowers. Later, he found that night blooming plants such as the Morning Glory, could keep blooming if exposed to blue light, but when they were exposed to pinkish light their blooms collapsed.

All of this seems to be converging on the idea that the female reproductive tissues are activated by a free-radical or excited electron promitotic system. But beyond that it seems to have clear implications for aging, stress, toxicity, energy, tissue repair, regeneration, etc. The key idea is that biological structure and biological energy are delicately linked and balanced even at the finest—molecular and submolecular—levels.[§]

[†] In "A Biophysical Approach to Altered Consciousness"[1] I proposed that a "leak" from this system could cause mental symptoms. Substances such as progesterone might have their beneficial psychological and neurological effects by stopping the leak.

[‡] In the winter of 1954–55 I experimented with growing algae under various lights—red, blue, and ultraviolet—to compare with algae grown in daylight, but I didn't have facilities for growing larger plants under those lights, and it has taken more than 30 years to get back to it.

[§] Szent-Györgyi invented this field, called submolecular biology. It shades into Selye's "supra-molecular" biology through the work of many people, such as Gilbert N. Ling, F.Z. Meerson, and Otto Warburg.

Taxol, Yew & Cancer

Townsend Letter for Doctors, February/March, 1992

THE U.S. Government has given a drug company a monopoly on the exploitation of the rare and slow-growing yew tree, to make a "cancer drug." People who question the propriety of this deal hesitate to speak out, because they feel they might be depriving some woman with ovarian cancer of "the chance to live."

We should remember that our cancer establishment, the alliance between government and the medical/pharmaceutical industry, has been claiming victory against cancer for several decades, while the death rate from cancer has steadily increased. This discrepancy between their claims and reality can be understood with the help of three facts:

1. By increasing the number of people diagnosed as having cancer, the "cure" rate can be increased. Every middle-aged person has some tissue that could be diagnosed as "cancerous." Soon, magnetic resonance imaging will be so sensitive that most of those "cancers" can be found, and the "cure rate" will rise to about 90 %, but the death rate from cancer won't decline.

2. The baby-boom that followed World War II caused the rate of increase in cancer mortality to decline, because most cancer occurs in older people, and they were becoming a smaller percentage of the whole population. The same tricks used by the cancer industry could allow someone to claim that the "standard" lifespan was now about 92 years. Although this is statistical fraud of the crudest sort, it has been consistently accepted and promoted by university scientists of the "first rank," who benefit financially from the misrepresentation.

3. The same baby-boom caused an increase in childhood leukemia. At the same time, radiation from atomic bomb testing and prenatal X-rays caused a real increase in the risk of leukemia. The American Cancer Society used 1940 for "age-standardization" to make the general cancer rate look better, but they re-standardized when talking about childhood leukemia, so their calculations would show a downward trend. The downward trend in childhood disease was naturally produced by a declining birthrate, the end of the baby boom, but it was undoubtedly reinforced by the end of atmospheric nuclear testing and by the decreased

use of prenatal X-rays. But these figures are the basis for the cancer industry's main claims of success.

Many poisons can cause tumors to shrink, and the yew tree contains such poisons. But shrinking a tumor has nothing to do with increasing a patient's survival prospect. The quack-busters have made that point many times in attacking "unproven cancer remedies."

At best, taxol is an unproven cancer remedy, but when a drug monopoly is promoting a new product, facts hardly matter.

The mechanism of taxol's cytotoxicity is probably similar to that of colchicine, namely, interference with the microtubule system. Microtubules are essential for cell division and many other cell functions. The goal of cytotoxic chemotherapy is to block cell division in cancer, without destroying cell division in essential tissues such as blood, the intestine's lining, skin, and the immune system. Certain cells of the immune system are uniquely fragile, and this fragility sometimes makes it possible to kill a cancer derived from those fragile cells, without killing the patient. The use of glucocorticoid hormones to destroy thymus-derived cancers takes advantage of that natural sensitivity and fragility.

Besides cell division, many (if not all) cellular functions depend on normal microtubule physiology. Microtubules are especially prominent in nerve cells. They are involved in axonal transport. It is not surprising that taxol is very toxic to nerve cells.[1,2] Microtubules are probably involved in the amoeboid movement of white blood cells, and taxol is very toxic to the neutrophils. Microtubules are involved in the fusion of their digestive enzyme vacuoles with their phagocytic vacuoles.[3] The neutrophils, effective tumor cell killers, would not be poisoned by a rational therapy. (These cells also govern wound healing and tissue remodeling, and I will discuss them later in relation to aging and regeneration.)

The metabolism of cholesterol into pregnenolone and progesterone (which are natural anti-cancer factors) is blocked by taxol.[4] Adrenalin secretion is also inhibited by taxol,[5] and adrenalin too, has some relevance to cancer control, e.g., it is anti-mitotic.

Certain cytotoxic treatments have a very rational basis. For example, cyanide poisoning followed by thiosulfate detoxification, is based on the fact that cancer cells consistently lack the enzymes for detoxifying cyanide by combining it with sulfur. Cyanide is too cheap to warrant serious consideration as a cancer therapy. (The pharmaceutical industry has undoubtedly considered promoting their cancer drugs to replace

cyanide in capital punishment, but so far death by torture is acceptable only for cancer patients.) The established specificity of cyanide/thiosulfate toxicity for cancer cells contrasts with the generalized toxicity of taxol, which could be classed with whole-body irradiation as a desperate and irrational approach.

One aspect of taxol research might advance our understanding of the body's defenses against cancer. It happens that taxol, like bacterial endotoxin, stimulates macrophages to secrete tumor necrosis factor (TNF). This knowledge might lead to an insight into the nature of the process that controls TNF, and how that process fits into normal immunity. Promoting the body's natural immunity, combined with reducing our exposure to cancer-causing factors, should have higher priority in the health sciences, but the power of the drug industry focuses attention on the idea of medically killing cancer cells.

William McGuire (Johns Hopkins School of Medicine) reported in 1989 that 12 patients out of 48 with "refractory" ovarian cancer[6] "responded" to taxol treatment. All but two of the patients were dead by July, 1991. Ninety-six percent mortality doesn't sound very good.

A study at the University of Pennsylvania Cancer Center[7] found that, in patients with extensive malignant disease, there was no difference in survival time for patients who got conventional treatment, and 78 similar patients who were treated with unorthodox methods at the Livingston-Wheeler Clinic. A growing number of physicians recognize the uselessness of most conventional treatments.

A 77 year-old friend of mine had a physical examination, and learned that he had prostate cancer, though there had been no symptoms. As soon as he was given estrogen "therapy," he became miserable, and was never comfortable again, and died of a stroke a few months later. He believed that the misery was "extending" his life, because that is what his physician told him. There is clear evidence that estrogen does not prolong survival in prostate cancer patients, and the often cited "research" which is said to show the efficacy of estrogen treatment was nothing but a survey of doctor's opinions. The survey was done at a time when it was believed that prostate cancer is caused by testosterone, and that estrogen antagonizes testosterone. In fact, animal experiments show that estrogen causes prostate cancer, and *in vitro* tests show that it, but not testosterone, stimulates cell division in human prostate tissue. Progesterone, which antagonizes both estrogen and testosterone, has

been used to shrink enlarged prostates, but estrogen continues to be used to treat prostate cancer.

If poisons are going to be used against cancer, they should be more toxic to the cancer than to the patient, and they should extend the patient's lifespan, and/or decrease suffering.

A very competent cancer researcher found that the patients who delayed longest in going for medical treatment for cancer had the longest survival. If patients would remind their doctors to "first do no harm," there might be fewer lives lost in the heroic "war against cancer."

The Bean Syndrome

Townsend Letter for Doctors, 1993

An extract of the common bean (phytohaemagglutinin, PHA) is widely used in research, and has been used occasionally in medicine. The effects of bean toxin, and other plant toxins (e.g., pokeberry) overlap in several ways with viral infection and autoimmune disease. PHA causes, for example, the appearance of large mononuclear cells in the blood, the suppression of DNA synthesis in thymic cells, a slight leucopenia, and hepatic necrosis. Extracts of lentils, broad beans, and fenugreek (used in curry) are as active as PHA, and extracts of common peas, chick peas, lupinus, and soy beans also have some activity. The effects of a single exposure (such as eating a pokeberry) can remain microscopically visible for two weeks.[1]

In aging, stress, and malnutrition, the barrier function of the intestine is weakened. Vitamin A and magnesium deficiencies allow macromolecules to enter the blood from the intestine.[2]

Injury to the bowel causes"flu-like" symptoms. There have been reports that the viruses of "respiratory diseases" appear in the intestine before they appear in the respiratory tract. Alvarez found that"when a dog gets distemper the gradient of latent period down its small bowel is reversed," and he suggests that in a cold"a systolic, non-progressive type of contraction appears." He says codeine is the best medicine to block a cold. (I have argued that it is vitamin C's laxative action which can interrupt cold symptoms.) Recent research shows that naloxone, the morphine antagonist, can restore normal responses to the stressed bowel. Alvarez was interested in chronic fatigue and"painful fatigue," and remarked that occasionally"a fatigue state will follow a bout with some infection such as influenza."[3]

Bacterial toxins, whether produced in the intestine or in the manufacture of food supplements, pass through the wall of the intestine in larger amounts in stress, malnutrition, and old age. Endotoxin suppresses mitochondrial respiration, and tends to produce a shock-physiology similar to that produced by endogenous hormones. I have mentioned before that I think endotoxin can be involved in the premenstrual syndrome, and I think it might even be involved in some breast syndromes.[4,5]

Two features of mitochondrial damage in severe stress (regardless of whether endotoxin is involved) are a depletion of the antioxidant reserves, and loss of the ability to convert cholesterol into the protective steroid hormones. Mitochondrial damage is more likely in hypothyroidism, as I have discussed previously; thyroxin inhibits lipid peroxidation, end it tends to be inversely related to adrenalin, preventing or minimizing"catecholamine toxicity," for example. Beans and lentils happen to be powerful anti-thyroid agents, so it isn't surprising to see indications of decreased aerobic capacity, resulting from decreased peak oxygen consumption[6] in association with the chronic fatigue syndrome (CFS), if that syndrome is caused by chronic exposure to dietary legumes.

Hypothyroidism causes poor magnesium retention, so the report that a magnesium supplement caused reduced pain and improved energy level and emotional state, while increasing intracellular magnesium in CFS patients,[7] suggests a role for hypothyroidism in CFS. One of the symptoms specific to chronic fatigue syndrome[8]—postexertional malaise, marked by pain and weakness and by an exacerbation of other symptoms including fever and adenopathy—can be explained as the result of increased absorption of bowel toxins which follows the relative ischemia of the intestine during intense adrenergic stimulation.

A day or more after eating an allergen, it can be resting harmlessly in the intestine, and exertion, or emotion, or hunger, or nighttime can lower the blood sugar enough to cause a surge of adrenalin. The adrenalin reduces the flow of blood to the intestine, allowing allergens to be absorbed via the de-energized tissues. If the blood sugar stays low in spite of the adrenalin, white cells will be stimulated to release histamine and other pro-inflammatory substances, but the adrenalin will also cause the secretion of glucocorticoids. Night-sweats and neurological symptoms can be produced by these hormonal responses. The glucocorticoids first induce, then—at high levels—destroy the detoxifying enzymes.

Special conditions, such as a bowel infection, or immaturity of the intestine, can allow large amounts of allergens to pass through the intestinal barriers. In Los Angeles, I learned that physicians and nutritionists often advise welfare mothers to start feeding beans to their babies at six months. In parts of Africa, babies are given"bean milk" from the

beginning instead of milk. The Epstein-Barr virus, which is believed[†] to cause Burkitt's lymphoma and infectious mononucleosis, has often been proposed as a cause of the chronic fatigue syndrome. R. J. V. Pulvertaft[9] found"a close similarity between Burkitt cells and human lymphocytes stimulated by bean extract." He concluded that"...the possibility of a relation between Burkitt's lymphoma and a diet of beans should not be neglected," though he emphasized that other factors must be considered, since most people who eat beans don't develop the disease. The intestinal parasites which are common in tropical Africa can cause inflammation of the bowel, leading to the absorption of large amounts of antigens.

Since the bowel becomes inflamed in influenza, it is reasonable to think that some of the symptoms of"the flu" are produced by absorbed bowel toxins. The variations in the post-influenza syndromes are very likely influenced by the nature of the bacteria or foods which are present, chronically or at the time of an uncompensated stress or inflammatory disease. K. M. Stevens[10] has argued that while rheumatic fever and glomerulonephritis are caused by the antigens of streptocci, systemic lupus erythematosis (SLE) is probably caused by the antigens of gram-positive lactobacilli found in the normal flora.

Migraine, SLE, CFS, thyroid problems, and some kinds of porphyria seem to be more common in women of reproductive age, and are often exacerbated by premenstrual hormone changes. According to Stevens,"SLE is almost entirely a disease of women of child-bearing age. One possibility for this selection could be that women during this period harbour a peculiar flora. This is indeed the case; large numbers of gram-positive lactobacilli are present in the vagina only during the thirty-odd years when regular menstrual activity is present." In 1974, I noticed that I consistently got a migraine headache after drinking a lactobacillus milk product, and stopped using (and recommending) yogurt and other lactobacillus foods, though I suspected it was the lactic acid which caused the symptoms. I still consider lactic acid to be a metabolic burden, especially when combined with an estrogen excess, but Stevens' main point, about the significance of our immunological response to systemic bacterial antigens, deserves more attention.

[†] Antibodies to this virus can be found In 90 % of the population, so it isn't very meaningful to say that it "causes" those particular conditions.

I have previously discussed the use of antibiotics (and/or carrot fiber and/or charcoal) to relieve the premenstrual syndrome, and have mentioned the study in which the lifespan was extended by occasionally adding charcoal to the diet. Recently, I heard about a Mexican farmer who collected his neighbors' runt pigs, and got them to grow normally by adding charcoal to their diet. This probably achieves the same thing as adding antibiotics to their food, which is practiced by pig farmers in the U.S. to promote growth and efficient use of food. Charcoal, besides binding and removing toxins, is also a powerful catalyst for the oxidative destruction of many toxic chemicals. In a sense, it anticipates the action of the protective enzymes of the intestinal wall and the liver.

Our normal defenses against environmental toxins include a surface layer of mucus, the IgA antibodies on membranes, the brush border of intestinal cells, on which protein digestion normally takes place, enzymes in the intestine and liver which hydoxylate and glucuronidate smaller molecules of toxins, and binding-proteins, such as albumin and metallothionein, all of which keep toxins from entering other parts of the body. When toxins get past those barriers, survival depends on other adaptive factors, including the catatoxic steroids and the antioxidative systems.[11,12] Besides metabolizing exogenous toxins, the detoxifying enzymes of the monooxygenase system metabolize endogenous substances, including steroids, prostaglandins, and polyunsaturated fatty acids, which affect allergic reactivity. An imbalance of this system can waste the protective steroids.[13]

Recently, it has been argued that the allergic reaction itself functions as an immunological defense against toxins.[14] However, when the intestine and liver are injured, the production of cholesterol is often decreased to such a great degree that there isn't enough to maintain adequate production of the catatoxic and anti-inflammatory steroids. Many people with the allergic fatigue syndrome have a dangerously Iow blood cholesterol level of 90 mg/dL to 130 mg/dL. (Fruit, because of its fructose content, usually helps restore liver cholesterol synthesis.)

Undercooked and raw plant materials in general are important sources of toxins and allergens. Legumes have recently become more important factors in the U.S. diet, because of a complex shift of ideology about the"healthful" diet, which is often associated with a compulsion to "exercise," and sometimes to use stylish, but toxic, food supplements such as tryptophan, iron, and manganese. Ascorbic acid tablets may be

contaminated with enough iron and/or other catalysts to produce a toxic amount of free hydroxyl radicals.[15] In a vegetarian diet containing very little vitamin A as retinol, carotene can sometimes become toxic, since its conversion to retinol requires vitamin B_{12} and other liver functions that seem to depend on adequate thyroid function, and excessive carotene can be anti-thyroid as well as anti-steroidogenic. A deficiency of retinol can damage the barrier functions or membranes, various immune functions including antibody formation, and the synthesis of protective steroids.

Some women with premenstrual fatigue have found that the"premenstrual" phase tends to get longer and longer, until they have chronic fatigue. I found that to be one of the easiest"PMS" problems to correct. When people are older, and have been sick longer, the fatigue problem is likely to involve more systems of the body. The larger the quantity of"toxic fat" stored in the body, the more careful the person must be about increasing metabolic and physical activity.

Using more vitamin E, short-chain saturated fats, and other anti-lipid-peroxidation agents is important.

Sixty years ago, people with chronic fatigue were often said to suffer from"nervous breakdown," and advised to go to a sanitarium for a vacation, and to stop bothering the doctor. A change of activity, of place, of work, or of associates can sometimes be very therapeutic. Changing the diet can have social and ideological overtones, and can be done more easily while on a vacation trip. But sometimes the problem can be solved simply by avoiding some vegetable materials and food supplements, and/or by correcting hormonal problems, and/or by modifying the intestinal ecology.

The Dire Effects of Estrogen Pollution

NaturoDoc, April, 2006

POLLUTION of the environment and food supply by estrogenic chemicals is getting increased attention. Early in the study of estrogens, it was noticed that soot, containing polycyclic aromatic hydrocarbons, was both estrogenic and carcinogenic. Since then, it has been found that phenolics and chlorinated hydrocarbons are significantly estrogenic, and that many estrogenic herbicides, pesticides, and industrial by-products persist in the environment, causing infertility, deformed reproductive organs, tumors, and other biological defects, including immunodeficiency.

In the Columbia River, a recent study found that about 25 % of the otters and muskrats were anatomically deformed. Estrogenic pollution kills birds, panthers, alligators, old men, young women, fish, seals, babies, and ecosystems. Some of these chemicals are sprayed on forests by the U.S. Department of Agriculture, where they enter lakes, underwater aquifers, rivers, and oceans. Private businesses spray them on farms and orchards, or put them into the air as smoke or vapors, or dump them directly into rivers. Homeowners put them on their lawns and gardens.

Natural estrogens, from human urine, enter the rivers from sewage. Many tons of synthetic and pharmaceutical estrogens, administered to menopausal women in quantities much larger than their bodies ever produced metabolically, are being added to the rivers.

In the same way that weak estrogens in the environment may become hundreds of times more estrogenic by synergistic interactions,[1] combinations of natural, medical, dietary, and environmental estrogens are almost certain to have unexpected results. The concept of a "protective estrogen" is very similar to the idea of "protective mutagens" or "protective carcinogens," though in the case of estrogens, their promoters don't even know what the normal, natural functions of estrogen are.

In November 1995, an international conference was held to study the problem of "environmental endocrine-disrupting chemicals" and devise strategies for increasing public awareness of the seriousness of the problem. Their "Statement from the Work Session" says: "New evidence is especially worrisome, because it underscores the exquisite sensitivity of the developing nervous system to chemical perturbations that result in functional abnormalities."

This work session was convened because of the growing concern that failure to confront the problem could have major economic and societal implications. "We are certain of the following: endocrine-disrupting chemicals can undermine neurological and behavioral development and the subsequent potential of individuals…" Because the endocrine system is sensitive to perturbation, it is a likely target for disturbance.

Man-made endocrine-disrupting chemicals range across all continents and oceans. They are found in native populations from the Arctic to the tropics, and, because of their persistence in the body, they can be passed from generation to generation. Many endocrine-disrupting contaminants, even if less potent than the natural products, are present in living tissue at concentrations millions of times higher than the natural hormones. The developing brain exhibits specific and often narrow windows during which exposure to endocrine disruptors can produce permanent changes in its structure and function.

In spite of this increased exposure to estrogens, there is a new wave of advertising of estrogenic substances, based on the idea that weak estrogens will provide protection against strong estrogens. The environmental background of estrogenic pollution already provides a continuous estrogenic exposure. In the 1940s, Alexander Lipshuts demonstrated that a continuous, weak estrogenic stimulus was immensely effective in producing, first fibromas, then cancer, in one organ after another, and the effect was not limited to the reproductive system.

How is it possible that the idea of "protection" from a weak estrogen seems convincing to so many? Isn't this the same process that we saw when the nuclear industry promoted Luckey's doctrine of "radiation hormesis," literally the claim that "a little radiation is positively good for us"?

DES (diethylstilbestrol) is one of the most notorious estrogens, because studies in humans revealed that its use during pregnancy not only caused cancer, miscarriages, blood clots, etc., in the women who used it but also caused cancer, infertility, and deformities in their children and even in their grandchildren. (But those transgenerational effects are not unique to it.)

Besides the absurd use of DES to prevent miscarriages, around 1950 it was also used to treat vulvovaginitis in little girls, for menstrual irregularity at puberty, to treat sterility, dysfunctional bleeding, endometriosis, amenorrhea, oligomenorrhea, dysmenorrhea, migraine headaches, nau-

sea, and vomiting, and painful breast engorgement or severe bleeding after childbirth.

DES is a "weak" estrogen in the sense that it doesn't compete with natural estrogens for the "estrogen receptors." (Estriol binds more strongly to receptors than DES does.[2]) Pills formerly contained 5 mg to 250 mg of DES. The 1984 PDR lists doses for hypogonadism and ovarian failure as 0.2 mg to 0.5 mg daily. In general, the dosage of estrogens decreased by a factor of 100 after the 1960s.

An aggressively stupid editorial by Alvin H. Follingstad[3] is being circulated to promote the use of estriol, or phytoestrogens. It argues that women who secrete larger amounts of estriol are resistant to cancer.

By some tests, estriol is a "weak estrogen"; by others, it is a powerful estrogen. When estriol was placed in the uterus of a rabbit, only 1.25 μg was sufficient to prevent implantation and destroy the blastocyst.[4] Since the effect was local, the body weight of the animal doesn't make much difference when thinking about the probable effect of a similar local concentration of the hormone on human tissues. The anti-progestational activities of estriol and estradiol are approximately the same.[5]

When 5 mg of estriol was given to women intravaginally, this very large dose suppressed LH within 2 h and suppressed FSH within 5 h. Orally, 8 mg had similar effects on LH and FSH after 30 days and also had an estrogenic effect on the vaginal epithelium. These quick systemic effects of a "weak estrogen" are essentially those of a "strong estrogen," except for the size of the dose.[6]

When administered subcutaneously, estriol induces abortions and stillbirths.[7]

Another indication of the strength of estrogen is its ability to cause the uterus to enlarge. Estriol is slightly weaker, in terms of milligrams required to cause a certain rate of uterine enlargement, than estradiol.[8] But isn't the important question whether or not the weak estrogen imitates all of the effects of estradiol, including carcinogenesis and blood clotting, in addition to any special harmful effects it might have?

When added to long-term cultures of human breast cancer cells, estriol stimulated their growth and overcame the antiestrogenic effects of tamoxifen, even at concentrations hundreds of times lower than that of tamoxifen. "The data do not support an antiestrogenic role for estriol in human breast cancer."[9]

Studies of the urinary output of estriol and estradiol in women with or without breast cancer do not reliably show the claimed association between low estriol and cancer, and the stimulating effect of estriol on the growth of cancer cells suggests that any alteration of the estrogen ratio is likely to be a consequence of the disease rather than a cause. The conversion of estradiol to other estrogens occurs mainly in the liver of the non-pregnant woman, as does the further metabolism of the estrogens into glucuronides and sulfates.

The hormonal conditions leading to and associated with breast cancer all affect the liver and its metabolic systems. The hydroxylating enzymes are also affected by toxins. Hypothyroidism (low T_3), low progesterone, pregnenolone, DHEA, etiocholanolone, and high prolactin, growth hormone, and cortisol are associated with the chronic high estrogen and breast cancer physiologies, and modify the liver's regulatory ability.

The decreased output of hormones when the fetal-placental system is dying is a natural consequence, since the placenta produces hormones and during pregnancy converts estradiol to estriol. Since estradiol in excess kills the fetus, its conversion by the placenta to estriol is in accord with the evidence showing that estriol is the more quickly excreted form.[10] The conversion of 16-hydroxyandrostenedione and 16-hydroxyDHEA into estriol by the placenta[11] would also cause fetal exhaustion or death, resulting in lower estriol production.

But a recent observation that a surge of estriol production precedes the onset of labor and that its premature occurrence can identify women at risk of premature delivery[12] suggests that the estriol surge might reflect the mother's increased production of adrenal androgens during stress. (This would be analogous to the situation in the polycystic ovary syndrome, in which excessive estradiol drives the adrenals to produce androgens.)

Estetrol, which has one more hydroxyl group than estriol, is a "more sensitive and reliable indicator of fetal morbidity than estriol during toxemic pregnancies" because it starts to decrease earlier or decreases more than estriol.[13] This seems to make it even clearer that the decline of estriol is a consequence, not a cause, of fetal sickness or death.

A 1994 publication[14] reported that there are four hormonal features in women with breast cancer: diminished androgen production, luteal

inadequacy, increased 16-hydroxylation of estradiol, and increased prolactin. The 16-hydroxylation converts estradiol into estriol.

A new technique for radiographically locating a hormone-dependent breast cancer is based on the fact that estriol-sulfate is a major metabolite of estradiol. The technique showed the tumor to have about a six-fold higher concentration of estriol-sulfate than liver or muscle.[15]

Another association of elevated conversion of estradiol to estriol with disease was found to occur in men who had a myocardial infarction, compared to controls who hadn't.[16]

The estrogens in clover have been known for several decades to have a contraceptive action in sheep, and other phytoestrogens are known to cause deformities in the genitals, feminization of men, anatomical changes in the brain, as well as functional masculinization of the female brain.[17–20] The effects of the phytoestrogens are very complex because they modify the sensitivity of cells to natural estrogens and also modify the metabolism of estrogens, with the result that the effects on a given tissue can be either pro-estrogenic or anti-estrogenic.

For example, the flavonoids naringenin, quercetin, and kaempherol (kaempherol is an antioxidant, a phytoestrogen, and a mutagen) modify the metabolism of estradiol, causing increased bioavailability of both estrone and estradiol.[21]

Why do plants make phytoestrogens? There is some information indicating that these compounds evolved to regulate the plants' interactions with other organisms—to attract bacteria, or to repel insects, for example, rather than just as pigment-forming materials.[22] The fact that some of them bind to our "estrogen receptors" is probably misleading because of their many other effects, including inhibiting enzyme functions involved in the regulation of steroids and prostaglandins. Their biochemistry in animals is much more complicated than that of natural estrogens, which is itself so complicated that we can only guess what the consequences might be when we change the concentration and ratio of substances in that complex system.

These "natural" effects in sheep were forerunners of the observed estrogenic effects in wild animals, caused by pollutants. Twenty-five years ago I reviewed many of the issues of estrogen's toxicity and the ubiquity of estrogenic substances, and since then I have regularly spoken about it, but I haven't concentrated much attention on the phytoestrogens because we can usually just choose foods that are relatively free of them.

They are so often associated with other food toxins—antithyroid factors, inhibitors of digestive enzymes, immunosuppressants, etc.—that the avoidance of certain foods is desirable.

Recently, an advocate of soybeans said, "If they inhibit the thyroid, why isn't there an epidemic of hypothyroidism in Asia?" I happened to hear this right after seeing newspaper articles about China's problem with 100,000,000 cretins. Yes, Asia has endemic hypothyroidism, and beans are widely associated with hypothyroidism.

When I first heard about clover-induced miscarriages in sheep, I began reading about the subject because it was relevant to the work I was doing at that time on reproductive aging. Sheep, which are adapted to living at high altitudes, where all animals have reduced fertility, have an adaptive type of hemoglobin with a greater affinity for oxygen. Fetal hemoglobin, in animals at sea level, has a great affinity for oxygen, making it possible for the fetus to get enough oxygen, despite its insulation from the mother's direct blood supply. The high-altitude-tolerant sheep have hemoglobin, which is able to deliver sufficient oxygen to the uterus to meet the needs of the embryo or fetus, even during relative oxygen deprivation. These sheep are able to sustain pregnancy while grazing on clover. It seemed evident that estrogen and high altitude had something in common, namely, oxygen deprivation, and it also seemed evident that these sheep provided the explanation for estrogen's abortifacient effects.

Estrogen's effects, ranging from shock to cancer, all seem to relate to an interference with the use of oxygen. Different estrogens have different affinities for various tissues, and a given substance is likely to have effects other than estrogenicity, and the presence of other substances will modify the way a tissue responds, but the stressful shift away from oxidative energy production is the factor that all estrogens have in common. Otherwise, how could suffocation and X-irradiation have estrogenic effects?

Pharmaceutical misrepresentations regarding the estrogens rank, in terms of human consequences, with the radiation damage from fallout from bomb tests and reactor leaks, with industrial pollution, with degradation of the food supply—with genocide, in fact.

Advertising gets a bad name when it can't be distinguished from mass murder. At a certain point, we can't afford to waste our time making subtle distinctions between ignorance and malice. If we begin pointing out the lethal consequences of "stupid" or "quasi-stupid" commercial

or governmental policies, the offenders will have the burden of proving that their actions are the result of irresponsible ignorance rather than criminal duplicity. From the tobacco senators to the chemical, pharmaceutical, food, and energy industries and their agents in governmental agencies, those who do great harm must be held responsible.

The idea of corporate welfare, in which public funds are given as massive subsidies to rich corporations, is now generally recognized. Next, we have to increase our consciousness of corporate responsibility and recognize that ordinary criminal law, especially RICO, can be directly applied to corporations. It remains to be seen whether a government can be made to stop giving public funds to corporations, and instead, to begin enforcing the law against them—and against those in the agencies who participated in their crimes.

In the U.S., the death penalty is sometimes reserved for "aggravated homicide." If those who kill hundreds of thousands for the sake of billions of dollars in profits are not committing aggravated homicide, then it must be that no law written in the English language can be objectively interpreted, and the legal system is an Alice-in-Wonderland convenience for the corporate state.

Notes

As a result of industrial promotion, including product advertising and grants for research, "weak estrogens" and "antioxidants" derived from soy are being discussed as means to prevent breast and prostate cancer, heart disease, stress, and aging. Another so-called weak estrogen, estriol, is being promoted by drug companies for the "alternative medical" market, with the circulation of an editorial from *JAMA* recommending it for preventing breast cancer.

Japanese women used to be very free of breast cancer, and when their children grew up in the U.S., their incidence of the disease was like that of Americans. How odd that the soybean should be singled out for responsibility. Japanese breast cancer incidence has risen sharply in recent years. Did they stop eating tofu? Did their traditional use of seaweed as food have nothing to do with their health? Did the traditional home-bound isolation of Japanese women, their avoidance of smoking and drinking, have no effect on hormones and cancer? Their calorie

intake? Iodine and trace minerals? What types of protein and fat, and in what quantities, did they use?

The Edema of Stress

Townsend Letter for Doctors, May, 1989

OUR medical culture is bloated with retained errors—especially in connection with tissue water and its regulation. Sometimes, just by finding and eliminating errors, a new pattern will reveal itself in the remaining data.

A popular laboratory assignment for students in physiology is to drink a liter of ordinary or distilled water, and to measure the urine output in the next few hours. Then, in the next class (or with different students), a liter of water with 9 g of sodium chloride is drunk. The urine output over the next several hours is about a liter less than in the first experiment. Thus, "sodium causes water retention."

Textbooks base everything on this simple idea that "water follows sodium." "There are," they say, "no water pumps, only sodium pumps in cells."

Two real-world observations reveal the nature of the mistake in that doctrine.

People who work hard in the summer have noticed that their sweat can be so salty that it leaves salty crystals on their hair, and burns their eyes. They may need salt tablets during the day to keep from fainting. But other people, on a low salt diet, can sweat copiously without losing much salt. The body obviously adjusts its salt retention to compensate for salt intake.

By experiment, this adjustment takes only a couple of days. If physiology labs extended their experiments, they would find that sodium does not cause water retention in any sense that matters physiologically. In fact, in both animal and human studies, there are situations in which increased sodium helps to unload excess tissue water.[1,2]

The second real-world observation is that millions of women (in my direct observation, several hundred) have severely restricted their salt intake, yet continue to suffer from cyclic edema. Because of the assumption that "water follows sodium," and that body fluids are "isotonic" (with "isotonic" salt solutions, or with intracellular fluids), people seldom measure the osmolarity of blood plasma or serum. Estrogen causes the retention of water independently of sodium, causing the

molarity of the plasma to decrease. Uremia and, in general, old age cause the molarity of the blood to increase.

Seeing that salt restriction never helped women with cyclic edema, I explained the mechanisms of water regulation, first to just one woman. Within a month, she was salting her food to taste (i.e., salting it heavily in the premenstrual week), and having no trouble with edema. Since then (1978) I have explained this to many women, and it always works for estrogen-induced cyclic edema, and also for the edema of pregnancy induced by excess estrogen,[3] and for the occasional older person for whom it seems appropriate.

Serum albumin with its associated sodium ions, exerts a colloid osmotic pressure which is important in holding water inside blood vessels. Without its associated sodium ions, its intravascular effect is weakened, while the sodium-deficient water tends to cause cellular swelling.

Swelling of tissue cells is the kind of edema which is a serious problem in brain injury and stroke,[4] as well as in traumatic or toxic injury to other tissues, and whenever there is an inadequate supply of energy to cells,[5] as in hypoxia. At a certain point, the resulting pressure of swollen cells outside capillaries can no longer be compensated by adjustments in the blood vessels and increased blood pressure, with the result that tissue perfusion, nutrition and oxygenation are insufficient. (Thus, a severe sodium deficiency contributes to cellular hypoxia.)

When cells can't maintain their energy, they swell if exposed to a standard osmotic environment. This is the ordinary "edema of hypoxia," which is similar to the swelling of cells in tissue culture in "normal isotonic medium."

The conventional story to explain this swelling of hypoxia is that the "sodium pump" requires energy to keep the sodium out, and that inadequate energy allows water to "follow the sodium" into the cell. This explanation is wrong and misleading. While energy deficiency causes cells to swell abnormally, water is also retained by normal cells under the influence of energy. Much of the cell's energy, in the form of protein-bound ATP, regulates the colloidal nature of the cell, including its water content.[6] In this well-tested view of the cell, it would be appropriate to say that "sodium follows water," to contrast its medical implications to those of the "sodium pump" theory, and to create an image of the potentially protective function of sodium.

The generalized edema of hypoxia is closely related to the focal edema which occurs in inflammations and cancers.[7] In a focus of inflammation, the local metabolism, especially of glucose, increases to compensate for a loss of energy. (In a cancer cell, glucose consumption is often several times higher than that of a muscle cell in maximal activity). The focus becomes acidic. The provoking stimulus causes the ATP-protein complexes to break down, with production of ADP and phosphoric acid, and with changes in protein conformation. The increased dispersion of colloids, and the concentration of metabolites such as lactic acid, ammonia, ADP and phosphate, increase the osmotic and oncotic pressure of the cells. The osmotic pressure can be twice normal.

As early as 1920, there were studies of the extremely high osmotic pressure of serum from uremic patients. If there is systemic hypoxia, this very high osmotic pressure of the blood can be seen as a lucky—or adaptive—defense against the tendency of tissues to swell. Circulation can be maintained under conditions which otherwise would cause tissue swelling and compression of capillaries. Urea is used as a "diuretic" to treat edema of the brain in some circumstances, but it should probably be used more often. A small amount of DMSO (e.g., 1.5%) similarly causes cells to shrink.[8] This would seem to explain much of its anti-inflammatory action (yet the doctrine of "membrane pumps" says that permeant solutes shouldn't cause cell shrinkage). The use of hypertonic urea[9,10] or DMSO, or glucose (about 400 mg/dL, for example[11]) to treat cancer would help to restore circulation, prevent the adaptive leakage of proteins from cells, and allow normal regulatory processes to function more efficiently.

Serum albumin is one of the body's most powerful tools in maintaining homeostasis. Gilbert Ling has demonstrated that serum albumin or collagen, when "denatured" by urea, has a greatly increased oncotic pressure, or tendency to retain water.[12] Under physiological conditions, it is probably a variety of solutes, especially free fatty acids, which cause albumin to adjust its oncotic pressure.

I think the extremely quick changes that sometimes occur in extracellular connective tissue substance (e.g., in arthritis, exophthalmia, or glaucoma) in response to progesterone, pregnenolone, DHEA, or other related steroids, are likely to result from a similar physical effect on the colloidal osmotic pressure of the body fluids, and possibly of the

connective tissue substances themselves. Diffusion of oxygen through the lungs can be obstructed by layers of colloidal material, and steroids are involved in mitochondrial structure and stability and other cellular processes, so I don't mean to deny that these hormones also have other powerful effects, just that some early effects in relatively inert tissues are so quick that shifts in water content seem to be the best explanation.

Knowing that old organisms are relatively dehydrated, it is interesting to see that when a young muscle is made to lose some of its water, it functions similarly to a muscle from an old animal.[13] Recently, enzymes from old animals were denatured, causing them to lose their specific folded arrangement. When they were carefully "renatured," it was found that their enzymic function had increased, to become the same as that of enzymes from young animals. This shows that the nature of the "solution" in the cell, the conditions under which the enzymes are synthesized, has subtly modified their shape. Restoring the cell's energy, which governs the cell's colloidal state, might be able to restore all cellular functions to the active, young state, though this state would have to be maintained until protein "turnover" had renewed a large part of the cell structure. ("Protein turnover" refers to the normal process of renewal, in which some proteins are destroyed while new ones are being made).

Energy, in the form of ATP with magnesium, can be effectively supplied to tissues through the blood stream.[14–16] (Again, it has been the dogma of the "semi-permeable cell membrane" which has blocked the acceptance of this work: ATP simply couldn't get into cells, they said).

Energy, produced under the influence of the thyroid hormone (triiodothyronine, T_3), and acting to eliminate edema, can correct many problems that don't seem to have anything to do with "energy." The carpal tunnel syndrome, involving swelling in or around nerves, is often relieved by a thyroid supplement, or by avoiding anti-thyroid foods such as beans and seed oils. (Surgery to relieve the pressure caused by swelling is the conventional treatment).

Several people with a diagnosis of "multiple sclerosis" recovered immediately and fully when given thyroid. (Triiodothyronine does influence myelination,[17] but I think the important causal sequence is: first, disturbed respiration, then edema, then demyelination).

Many animal diseases, produced by copper deficiency and its associated respiratory defect, involve swelling of the brain and/or spinal cord.

Dogs, horses, and sheep develop weakness or paralysis of the hind legs, as a result of compression of the edematous spinal cord. In chronic copper deficiency, cells absorb an excess of iron,[18] so treatment isn't just a simple matter of giving supplementary copper.

Hyperoosmotic therapy, to directly relieve the swelling and restore circulation, would probably have to be the first step. In treating either hypoxia or iron-overload, there is the danger of tissue injury from the free radicals produced by reduced iron.

There are many practical, simple consequences of recognizing the interactions of osmotic pressure, metabolism, and inflammation. For example, people with inflammation of the bowel, resulting in obstruction that can't be relieved by an ordinary enema, have found that a hyperosmotic enema (sometimes with aspirin added) can relieve the edema which is causing the obstruction.

The Generality of Adaptogens

Townsend Letter for Doctors, 1991

THERE are far more sensory nerves entering the brain, than motor nerves leaving the brain. Generalization and judgment intervene between the complexity of sensation and the coherence of behavior. Encountering an infinite world, we marshall our resources for an adequate response. For me, this "sensory domination" of the brain is an important metaphor that offers some insight into other systems, because it suggests that interesting events of integration might be happening "above" the easily observable mechanical behavior of a particular system that we are trying to understand.

To bring generality to the understanding of cellular resistance, we should look for events that commonly occur during successful or unsuccessful responses to stressors of various types. Several years ago, someone found that a "final common pathway" of cellular death was the absorption by the cell of a large amount of calcium, when the cells were injured in a variety of ways. Working with the stressed heart, F. Z. Meerson spoke of the "calcium triad," suggesting that there are ways to interrupt the progress of cellular death even after it has started. Calcium activates proteinases, phospholipasis, ATP-ases, contraction and oxidative peroxidation, and uncouples oxidative phosphorylation, so that numerous drugs can interfere with various aspects of the cellular death process after it has begun. Knowing that calcium is a normal activator of muscle contraction and other normal processes, we can consider the normal physiological controls over calcium, as places where a little extra support might keep our cells safely away from the "final common pathway" of cell death.

In different situations, we can see different components of a "terminal" process. For example, iron tends to accumulate with age, and areas of calcification in soft tissue typically show iron associated with the calcium. (This association is probably both physicochemical and pathophysiological.) Vitamin E is protective against the lipid peroxidation induced by iron,[1] as well as that stimulated by calcium. Mice killed by a variety of methods show a high level of histamine in their tissues, suggesting that histamine might be involved in a "terminal pathway" on either the organismic or the cellular level. Histamine can stimulate the

entry of calcium into cells.[2] On the organismic level there are hormonal changes that accelerate the progress into a terminal state, and several of these are closely associated with the metabolism of calcium (cortisol, prolactin, and estrogen). Others are associated with the suppression of thyroid function.

Adaptogens are chemicals which increase an organism's ability to resist stress without suffering cumulative damage. This is a useful definition, since it excludes the glucocorticoids, which promote adaptation and short term resistance to stress, but do so at the expense of the organism's future reserves. Every aspect of our normal resistance that precedes our resort to cortisol can suggest possible classes of adaptogenic substances to strengthen those functions. The avoidance, binding, and detoxifying functions are all part of adaptation, but the most important aspect of adaptation is the ability to maintain a high level of tissue energy, and the stabilization of respiratory energy production is needed for that. Besides the oxidative production of energy, we need to prevent the wasteful expenditure of energy, and this requires the ability to raise thresholds to stimulation. (We can see both of these processes working in the adaptation of a healthy child to a serious infection: having a fever, and sleeping.)

As soon as something interferes with the oxidative production of energy (not having enough oxygen, for example, as when running) we adapt biochemically first by increasing the consumption of glucose for glycolytic energy production. This increased consumption of glucose tends to lower the concentration of glucose in the blood, and this (or various other signals, such as pain or fear, that are associated with the need for more glucose) causes the secretion of adrenalin, which can mobilize glucose from the liver's glycogen stores. If the glucose stores are depleted, the body resorts to the secretion of cortisol, to provide glucose (and other material) by cannibalizing protein from tissues which are momentarily less essential.

Both adrenalin and ACTH mobilize fat from storage. Stress-mobilized fatty acids contribute to the increased lipid-peroxidation seen during stress, and they also tend to damage mitochondria. The large increase in the death rate from asthma in the last decade or two is

now believed[†] to be the result of cardiovascular damage caused by the common use of inhalants containing catecholamines. Isoproteron01, a commonly used bronchodilator, causes mitochondrial damage, which can be prevented by blocking the carnitine-dependent oxidation of fatty acids. Since carnitine is required for the oxidation of long-chain fatty acids, its analog-betaines (which interfere with its transport of fatty acids into the mitochondria) protect against the damage that normally results from stress-induced (or catecholamine-induced) fatty acid oxidation. Since saturated fats protect against the cardiac necrosis produced by corn oil, I think it is probably lipid-peroxidation resulting from rapid oxidation of unsaturated fats which causes the heart damage in both catecholamine damage[3] and corn-oil toxicity. Vitamin E, coconut oil, and the carnitine antagonists (betaine derivatives) are adaptogens that protect respiration by directly decreasing lipid-peroxidation.

Uncompensated stress or injury is a complex process, so it shouldn't be suprising that adaptogens have a "broad spectrum" of beneficial biological effects, but it is precisely the breadth of vitamin E's effect that have made many physicians reluctant to use it, because they are trained to think in terms of "lock and key" specificity in pharmacology. The same reaction can be expected from drug-dominated medicine, as results with other adaptogens are published. For example, a Soviet adaptogen of the betaine class which is used as a feed-additive for animals, has been reported:

- induce interferon and protect against influenza virus,
- protect the brain against hypoxia,
- promote healing of wounds, burns, and sores,
- activate immune responses,
- promote cell division in thymus and spleen,
- restore contractility to hypoxic heart tissue,
- increase the contractile capacity of the heart by increasing ATP concentration,
- prevent decrease of ATP levels under various conditions,
- reduce isoproteronol or catecholamine-induced myocardial injury,
- protect the heart against fatty diets,

[†] Of course, the now discontinued use of sulfite preservative (approved and required by the FDA) in asthma drugs contributed to that high mortality.

- promote methylation of chromatin proteins,
- promote reparative and replicative DNA synthesis,
- increase translation of nucleic acids (protein synthesis),
- stimulate the rate of growth in chickens,
- have very low toxicity, and
- be suitable for use in treating a wide variety of cardiovascular diseases, such as cardiac insufficiency, myocarditis, cardiosclerosis, ischemic heart disease, and arrhythmias of varying etiology, and to have long-lasting positive inotropic effect, and cardiac-dilating activity.[†]

Since the substance seems to be a natural plant growth regulator, and to be cheap to produce, it is probably going to meet serious resistance from the drug industry/FDA monopolists, though the meat industry is likely to eventually find that it replaces many of the toxic chemicals that are now used.

The adaptogens of Eleutherococcus and ginseng are already in wide use. It is assumed that their steroidal components support the functions of our own protective steroids. These functions (normally adequately sustained by our endogenous steroids) are probably catatoxic, anticatabolic, anti-inflammatory, and osmoregulatory. Since there is so much talk about catabolic or anabolic steroids, it's important to say something about the anti-catabolic aspect of the protective or adaptogenic steroids.

On a time scale longer than that of the immediate stress experience, preventing cumulative damage is just as important as blocking the immediate injury process. Since cortisol, which is life-saving on the short time scale, is a major cause of cumulative damage to the organism, it is important to investigate things which will limit its chronic catabolic effect.

Although testosterone is very catabolic for the thymus gland, it is anabolic for muscle, and there is some evidence that it is directly competitive with cortisol, which is catabolic for muscle. When radioactive testosterone was injected into a person, the experimenters were surprised to find that its main concentration was in the heart muscle, rather than in the skeletal muscle. This high concentration of testosterone in the heart muscle suggests that an antagonistic relationship between testosterone

[†] Literature search by P. Hockstaff.

and cortisol is responsible for the ability of the heart to retain its protein while starvation or stress is causing protein to be removed from skin muscle, thymus, and other tissues, under cortisol's influence. Such an "anti-catabolic" effect must be especially important during the years of growth, so the youth-associated steroids (prenenolone, progesterone, DHEA) probably serve in this way, while being available for conversion into the more specific hormones. Plant steroids such as those in ginseng, having some structural similarity to the normal protective hormones, would serve as adaptogens by making up for a reduced amount of those normal youth-associated substances.

Filatov found that stressed tissues of both plants and animals produce protective and stimulating substances, which can be extracted for medical use. He identified succinic acid as a component of his extracts. Szent-Györgyi found that succinic acid stimulates respiration, which might explain why it promotes synthesis of pregnenolone and related steroids. It and fumaric acid are now considered to be adaptogens. Since succinic acid safely chelates toxic heavy metals out of mitochondria, it might also safely carry copper into the mitochondria. Succinic acid is also closely associated with GABA metabolism (gamma-amino butyric acid is converted to succinic semialdehyde in a transamination reaction), and so is probably complementary to the GABA analogs GHB (gamma-hydroxy butyrate) and its lactone (which has anti-viral activity). GABA analogs are now one of the most actively studied classes of adaptogens. GABA has a wide range of stress-blocking actions, including neural inhibition, progesterone promotion, and blood sugar regulation.

The "local anesthetics," which generally have a broad range of effects, are an important class of adaptogens. Procaine has been found to normalize almost every system studied.[†] Doses far too small to have an anesthetic effect have clear biological effects. Lidocaine is used to prevent heart arrhythmia, and acts partly by preventing excessive calcium uptake by the cells. The atropine family of drugs is structurally similar to the "local anesthetics," and also have a long history of use in treating sickness and stress. Most of these chemicals have anti-histamine actions that are probably relevant to their value as adaptogens. These chemicals can protect microcirculation against spasms produced by exhaustion or overstimulation. Light can also have this effect.[4]

[†] One large study was done at Edgemoor Geriatric Hospital, Santee, California, in 1960.

Promotion of synthesis and stabilization of the detoxifying enzymes is another function of some adaptogens. The catatoxic steroids do this, but since they also have an immediate protective effect (that could hardly involve the production of new enzymes), they probably have other mechanisms of action, such as improving the capacity for binding toxins of proteins such as albumin. Since even cholesterol has catatoxic action, I often advise people to eat more eggs for a variety of problems. The egg lipids (including phospholipids and cholesterol) enter the blood in microscopic particles, called chylomicrons. Synthetic "liposomes" are a pharmaceutical fad, promoted for their ability to transport various drugs, but the liposomes themselves (made from egg phosphatidylcholine and cholesterol) have anti-inflammatory and anti-bacterial actions. ("Anti-inflammatory action of liposomes,"[5]) I think we have to include dietary eggs in our list of adaptogens.

I have often described the thyroid hormone as the basic anti-stress hormone, because it is essential for respiratory energy production.[6] The ATP produced under the influence of the thyroid hormone binds magnesium, and is relatively stable in its presence. ADP, the lower energy phosphate that results when ATP loses one phosphate group, happens to bind calcium. Thus, the high energy state of the cell binds magnesium (when it is available), and the low energy state binds calcium. Many of the events that are said to involve "ion pumps" are just different "ion-binding states" of the cell. Both thyroid (to form ATP) and magnesium (to stabilize ATP) are essential for cellular resistance to stress.

Magnesium-ATP, and liposomal-ATP administered intravenously have been used successfully to treat shock and to restore mitochondrial function, and are undoubtedly powerful "adaptogens," but it is much more practical to ingest eggs, magnesium-rich foods, and a little thyroid, to get "cholesterol-liposomes" and magnesium-ATP. Creatine phosphate, which is normally an intracellular energy reserve in balance with ATP, has been found to prevent the heart damage caused by catecholamines.[3] Energy depletion (ATP and creatine phosphate) is probably the central event which precipitates the entry of excess calcium into the cell.[7]

Since many of the biochemical changes in aging are the same as those occurring in stress, the adaptogens tend to relieve the symptoms of aging. And to some extent, relieving the symptoms of aging tends to resist the forces that would otherwise push cells toward the "final common pathways." But the perfect adaptogen would be something

that systematically blocked the agents of damage before any damage had been done. The avoidance of toxins and other stressors (including darkness) should be taken care of before too much emphasis is put on the use of adaptogens. Substances that have one clearly defined adaptogenic function often turn out to have several useful functions. Caffeine, for example, promotes thyroid function, blocks both radiation and chemical carcinogenesis, and inhibits absorption of iron, which under stress has important dysadaptive function.

Filatov's approach, using complex extracts of stressed tissue, suggests that certain methods of food storage and preparation might increase their adaptogen content, e.g., broccoli stored in a refrigerator has much more vitamin C than fresh broccoli; cold-dark storage was one of the stressors Filatov used. The same principle might apply to the use of crude plant or animal drugs. Traditional foods used for convalescents might also include some empirical adaptogens—broths, egg-nog, fruit juice, custards, etc.

Thyroid: Misconceptions

Townsend Letter for Doctors, November, 1993

WHEN I describe some of the simple ways the thyroid gland works, I know that I'm not answering the questions most people have. In the last 50 years, a culture, a mythology, related to thyroid hormone has been manufactured in this country. Now and then, people send me *JAMA*'s latest contribution to that culture. The articles and advertisements in medical journals, and the more direct contacts between drug companies and physicians, have covered most aspects of thyroid physiology with a thick layer of misinformation. A very different story is found in journals of endocrinology, biochemistry, nutrition and metabolism, and in foreign books and journals.

Most of the misinformation is based on something true. If a similar preoccupation with possible harmful side-effects surrounded the rest of medicine as it does thyroid supplementation, medicine would disappear; if it surrounded dietetics, people would starve.

It is sometimes true that "if you take thyroid it will suppress your own gland." By overdosing people until the output of their own glands had gone to zero, it was possible to see what happened when the overdose stopped. Everyone's gland was functioning perfectly again within two or three days. Occasionally, a person whose pituitary isn't producing TSH will respond to thyroid supplementation with normalization of TSH and restoration of their own thyroid gland's function.

It is sometimes (but rarely) true that a person will seem healthy when his serum thyroxine level is near one of the extremes of the "normal" range (which is often given as between 4 or 4.5 μg/dL, and 12 or 14 μg/dL). The story behind that extreme range (imagine a similar "normal" variation for cholesterol, or sodium, or potassium, or anything biochemically important) has to do with a revision in the 1940s of the definition of "normal" to include 95 % of the population, based on the PBI measurement, which was later found to be irrelevant to thyroid functioning.

Thyroxine is often called "the thyroid hormone," in the same way that estrogen has been called "the female hormone." Progesterone is quantitatively and functionally the most important female hormone, and triiodothyronine, or liothyronine, is functionally the most important

thyroid hormone. It is the metabolically active derivative of thyroxine, somewhat as insulin is the activated form of proinsulin. When thyroxine is added to brain tissue *in vitro*, it suppresses respiration; but when triiodothyronine is added to any tissue, respiration is increased. Triiodothyronine (T_3) is mostly produced in the liver, depending on the availability of glucose to the liver, allowing a sensitive adjustment of metabolism to nutrition.

Armour thyroid, USP, is often said to be of imprecise dosage, but in fact every batch is biologically standardized, and studies have shown it to be reliably within 1 % of the labeled potency. The best known brand of the supposedly chemically precise levothyroxine, however, was for a long time 30 % below the labeled potency.

If the liver is the main source of the thyroid problem, then thyroxine pills can make the problem worse, by suppressing the portion of T_3 still coming from the thyroid gland. Armour thyroid, USP, Thyrolar, Euthroid, Proloid, and a few other products contain both thyroxine and T_3, in approximately the proportion secreted by a normally functioning gland.

Unsaturated oils interfere with thyroid function in several ways, including blocking the "digestive" proteolytic enzymes involved in the release of hormone from the globulin. Unsaturated fatty acids interfere with binding of the hormone to a transport protein, and with the conversion of T_4 to T_3 in the liver and in the pituitary. Linoleic and linolenic acids are roughly twice as toxic to these systems as oleic acid is. The tissue response to the hormone is inhibited by unsaturated fats in proportion to the number of double bonds in the fat. A deficiency of polyunsaturated fatty acids is anti-estrogenic, partly by allowing the thyroid-stimulated liver to excrete estrogen, and partly by failing to activate the pituitary secretion of gonadotrophins.

G. W. Crile found that the basal metabolism of the people in Yucatan, where coconuts are a staple food, is 125 % of that of people in the United States. Animal experiments show that coconut oil added to a normal diet can lower serum cholesterol levels. There is a very reliable inverse relationship between the level of serum cholesterol and thyroid hormone action. A major effect of thyroid is to control the conversion of cholesterol into steroid hormones and bile acids.

Thyroid promotes the formation of progesterone, which in turn promotes the secretion of thyroid hormones. Estrogen blocks their release from the thyroid gland, causing the gland to enlarge.

Iodine deficiency used to cause goiters in the United States, but now it is almost impossible to have an iodine deficiency in this country. Iodine supplements can suppress the formation of thyroid hormone, producing classical signs of hypothyroidism.

Hashimoto's thyroiditis is often diagnosed, without appropriate evidence. Even when correctly diagnosed, the knowledge isn't relevant to treatment. Thyroid cells contain estrogen "receptors," and estrogen inhibits thyroid secretion, and excess estrogen is involved in most "autoimmune" disease. Supplemental thyroid so easily normalizes estrogen and the immune system that it, with progesterone and pregnenolone and DHEA, should be considered as the cure for autoimmune diseases, including thyroiditis—at least until someone finds an "autoimmune" disease that doesn't respond to a balancing of these hormones.

Breast discomfort and even the secretion of milk not associated with pregnancy or parturition, produced by excess prolactin, can often be relieved by thyroid, especially when taken with vitamins A and E. The incidence of breast cancer is high in hypothyroid regions. Excess prolactin and excess estrogen are associated with each other, with breast cancer, and with hypothyroidism.

Most physicians know how to test the Achilles tendon reflex, but believe it is a poor indicator of thyroid function. Often, this is because they have observed the reflex contraction itself, rather than the relaxation rate, which gives a clear indication of the rate at which energy is regenerated in the muscle. The "T wave" or repolarization wave in the electrocardiogram gives a similar indication of lagging energy production in hypothyroidism. Magnesium retention by cells is dependent on thyroid hormone, and is essential for cell relaxation.

The rate of energy restoration is relevant to the tired brain, too. Insomnia is the most commonly troublesome symptom of menopause, and it usually responds immediately to a small bedtime dose of T_3, just as T_3 rapidly restores the normal quick relaxation rate to the calf muscles and heart muscle. (Two or three grams of sodium chloride taken at bed-time in a little broth, or juice or water, has a strong sleep inducing effect; it lowers adrenaline, promotes glucose absorption by the intestine, and has other antistress actions, including "sparing" magnesium.)

Thyroid permits energy to be produced efficiently from glucose, and hypothyroidism causes glucose waste leading to hypoglycemia, which in turn leads to excessive secretion of adrenaline. Adrenaline, like the synthetic drugs that mimic its actions, has been known to be toxic for many years. It mobilizes fatty acids from storage, and its most obvious toxicity is to the circulatory system.

The circulatory complications of diabetes were avoided in Broda Barnes' diabetic patients, who received thyroid supplements. In diabetes, glucose is unable to enter cells, and the body's response resembles that of hypoglycemia, secreting adrenaline and mobilizing fats from storage. Since a certain amount of intracellular glucose is needed before the liver can form T_3, diabetics, like hypoglycemics, or like anyone during starvation, are unable to activate the thyroid hormone.

Adrenaline secretion leads to cortisol secretion. The "Cushingoid" fat distribution, sudden balding, and other signs of hormone imbalance secondary to hypothyroidism are statistically associated with heart disease. Broda Barnes clearly showed the protective action of thyroid against heart disease.

Too much thyroid does cause enlargement of the heart. Meerson, and others, have shown that growth of the heart muscle is a normal process of adapting to an increased workload. In a more extreme situation, too much thyroid can cause relative starvation, arresting growth, by causing the tissues to "work" too intensely. When mice are given food containing 1 % thyroid by weight, they stop growing, but normal growth resumes if they are also given liver as a nutritional supplement. Rats that were given enough Armour thyroid to stop their growth (up to 0.7 % of their food) had bones that were slightly heavier than the bones of the rats on the normal diet that had grown at the normal rate. That is, even when the diet isn't adequate to sustain normal growth, hyperthyroidism doesn't necessarily cause osteoporosis. Very large doses of thyroxine, though, are not the same as hyperthyroidism. An often cited report on osteoporosis that was observed in a few women who were taking thyroxine, actually provided no clear data to support its conclusions, but it did illustrate two important fallacies: Failing adequately to take into account that women who take thyroid medication have a history of hypothyroidism, and ignoring that thyroxine reliably suppresses the pituitary TSH and thus decreases the T_3 secreted by the thyroid gland, but doesn't reliably increase the liver's formation of T_3. Hypothyroidism,

whether natural or promoted by administered thyroxine, retards bone remodeling and tissue repair in general. As hypothyroidism predisposes to excess cortisol effects, it must also be a common factor in "Cushingoid" osteoporosis.

When the thyroid is normal, vitamin A and cholesterol are used rapidly in forming progesterone. Carotene tends to accumulate in hypothyroidism, and it can bind to the cells of the corpus luteum, preventing the use of vitamin A to form progesterone. Adrenalin, cortisol, prolactin, and ACTH are likely to be elevated in hypothyroidism, and they have been proposed as inhibitors of ovulation or progesterone secretion. Estrogen is usually elevated in hypothyroidism, and can prevent implantation of the embryo, or cause miscarriage if implantation occurs. Adequate thyroid normalizes these anti-fertility factors, which is why it was considered the basic fertility hormone. It is also essential for the vitality of sperm cells.

Animals which are artificially made hypothyroid develop cystic ovaries, so it is reasonable to consider hypothyroidism as an important factor when women have cystic ovaries. Thyroid hormone's effects on all systems of the body—nervous, immune, digestive, excretory, respiratory, etc.—contribute to optimal fertility, and to the vitality of the offspring.

Exercise lowers the level of thyroid hormones, partly by accelerating their breakdown. The stress of winter appears to do the same thing, and most people (and animals) need much more thyroid in the winter than they do in the summer. Exercise lowers human (and some animals') fertility, and winter lowers animals' fertility. I think human fertility, as indicated by sperm count, for example, is likely to be lower in winter.

Because some estrogen is secreted in the bile, adequate fiber in the diet (oats, potato, or raw carrots, for example) and regular bowel function help to prevent the build-up of estrogen, which inhibits the thyroid. (Estrogen which has been excreted in the bile can be reabsorbed from the intestine if there is slow transit time and too little fiber.) A deficiency of B vitamins or protein is also known to prevent the liver from excreting estrogen. One of the ways in which starvation inhibits thyroid function is by damaging the liver function. Vegetarians are sometimes dangerously deficient in protein, and in that state the body is very resistant to thyroid hormone. Elevated serum calcium is probably one of the factors in creating a state of thyroid-resistance during stress.

Thyroxine can protect against lipid peroxidation, yet the hormone is essential for the normal oxidation of fat. One aspect of its "antioxidant" function is that it allows respiration in the mitochondria to consume the reduced (electron donor) substances, which otherwise can accumulate and be oxidized by stored iron, to start the free-radical attack on lipids.

There are many directly anti-thyroid substances, but the only directly thyroid-activating substances I know of are coconut oil, progesterone, and pregnenolone. The saturated fatty acids, especially the highly soluble smaller molecules found in coconut oil, probably tend to simply dilute and weaken the inhibition that is chronically exerted by the polyunsaturated fatty acids, but butyric acid seems to have some specific effects, such as facilitating the uptake of T_3 by nerve cells and shifting cells away from the expression of the stress-related proteins. Progesterone promotes the release of hormones from the thyroid gland, and by promoting the formation of glycogen, it probably supports the formation of T_3 by the liver. Pregnenolone, which is formed from cholesterol in the mitochondria, also normalizes thyroid function, probably partly by optimizing the balance of steroid hormones, and partly by stabilizing the enzyme systems of the mitochondria.

Transdermal Progesterone for Premenstrual Syndrome

Townsend Letter for Doctors, November/December, 1983

For many years, Katharina Dalton[1] has studied the use of progesterone therapy for the premenstrual syndrome. A typical patient may require ten or more progesterone injections per month, more or less permanently. While this is feasible (at least in some countries) it is not comfortable or convenient, in some cases leads to serious reactions at the injection sites, and in the United States would be too expensive for general use. When the syndrome is disabling, even the burden of frequent and expensive injections is usually seen as a welcome alternative. However, a less expensive and more pleasant form of administration could make the therapy available to millions of women who are now disabled for one or more days each month. We are reporting here on what we believe to be a satisfactory alternative to the injection or implantation of progesterone, namely, a solution of progesterone and vegetable oil in a lotion or "cold cream" base for transdermal use.

After animal experiments revealed that progesterone in vegetable oil was absorbed effectively through the skin, in 1977 we began experiments with women who suffered from the premenstrual syndrome.

The effectiveness of the transdermal (absorption) route of administration varies with the individual, but compares favorably with injections in the amount assimilated. Thickness of skin or degree of circulation in the skin (these can be very abnormal in hypothyroidism, for example) and the amount of adipose tissue apparently make some difference in the rate of absorption and response. When a small daily dose (e.g., 5 or 10 mg) is sufficient, this can be taken as about 250 mg of a 3 % cream rubbed into the throat, where it leaves no noticeable oiliness after a few minutes. For large doses, the appropriate amount can be applied to a larger area of skin after a hot bath, once or twice a day if necessary.

We have used transdermal progesterone therapy in two hundred women suffering from the full range of premenstrual symptoms, including migraine, acne, depression, mastalgia, edema, and lethargy, and we found that nearly all of the women, applying the lotion themselves, are able to find the appropriate dosage for controlling their symptoms. Occasionally, thyroid therapy, weight reduction, or change in some aspect

of life-style is necessary for complete relief from symptoms. We have learned that it is necessary to be very explicit in describing the amounts that can be used, while leaving it up to the patient to find the dose which controls her symptoms, because some women have an exaggerated idea of the power of a "hormone." We have learned, when some women said the progesterone had no effect, that they were applying it as sparingly as they would a rare perfume, just touching it to their wrists.

Another problem we have encountered is that a few women have trouble understanding how, if their edema is caused by "hormones," a "hormone" could relieve the edema. We have usually solved such problems by applying one dose (sometimes using a 25 % solution) in the office, and waiting thirty or forty minutes to make sure that it was large enough to take effect. Once having felt sudden relief from this "cold cream," it is easier for the patient to understand how it should be used.

Unfortunately, many of the solvents which hold progesterone stably in a concentrated solution are highly allergenic. Injectable progesterone in oil could be used transdermally except for this problem. Progesterone can be removed from an injectable water suspension, and dissolved in warm olive or almond oil for transdermal use in patients who react to other solvents.

Unsaturated Oils Have Deleterious Effects

Townsend Letter for Doctors, May, 1988

I agree with your recent remarks about directing criticism mainly toward the errors of conventional medicine, because the biggest problems exist within the orthodox and government-established medical system. As you said, people should not be put down because of their degrees, and for that reason I avoid putting letters after names, except when there is a reason for it. However, I got a letter from Charlotte Gerson criticizing me for failing to mention Budwig's degree. Since the other degrees (including mine) were editorially added to my letter, it wasn't my intention to slight Budwig for being degree deficient.

However, Charlotte Gerson also says that I made "a number of statements which are not defensible," but doesn't seem to understand what I said. I am aware that linseed oil has been used by Mexican physicians to treat cancer at least since 1939, and that it can be toxic to cancer cells (though probably less toxic than to normal cells),[†] and that its laxative action is plausibly effective in treating constipated cancer patients. My primary criticism is that people who get on the big marketing bandwagon (whether the product is linseed oil or germanium or iron supplements) so often—as in the Udo Erasmus book—appear to systematically lead attention away from the possible dangers of their product.

The "deleterious effects of unsaturated oils" have been clearly established and are recognized by everyone working in the field. They are not "supposed" and are not merely "discussed" subject to disproof "by others." Many people are now investigating a variety of theories that attempt to explain the specific nature of the toxicity.

The opinions credited to Budwig by Erasmus suggest ignorance of organic chemistry and biochemistry. If someone takes Dr. Budwig's ideas seriously, TL/D should invite her to explain them herself.

Without knowing more about the publication details of the new version of the book, *Fifty Cases*, and the letter that Max Gerson supposedly wrote to Schweitzer, I wouldn't want to analyze all of the ideas ascribed to him. The original book, which I believe was reprinted several

[†] Cancer cells are rich in antioxidants which protect them against free radicals.[1]

times without changes, even after his death, was a coherent scientific document. Posthumous "new editions" always raise questions.

Using Sunlight to Sustain Life

Townsend Letter for Doctors, June, 1996

Q: You mention sunlight as beneficial to your health. How?

For example, it can cure depression, improve immunity, stimulate our metabolism while decreasing food craving, and increase our intelligence.

Although exposure to sun does contribute to aging of the skin, people who spend years working outdoors have a reduced incidence of cancer of internal organs. For many years, it has been known that the death rate increases during the winter months and also increases at night (winter or summer). Most deaths occur just before dawn when the body is in its least efficient state. It is just in the last few decades that we have been learning the reasons for this beneficial effect of light. It turns out that daylight stimulates our ability to use oxygen for energy production, and protects our tissues from some of the free-radical toxins that are produced by normal metabolism, by stress, or by radiation.

While ultraviolet light, and even blue light, tend to suppress our cells' ability to produce energy, those types of light penetrate only a short distance into living tissue, and so it is mainly the skin which is damaged by too much sunlight. Since blood does circulate in the layers of skin which receive ultraviolet rays, prolonged sun exposure can damage the immune system by injuring white blood cells, but usually the stimulating effect of the other types of light that penetrate more deeply offset this effect on the immune system.

Many health food stores are now selling melatonin, to reduce sleep and "prevent cancer." They have taken some information out of context, and don't realize how dangerous melatonin is. It makes the brain sluggish, causes the sex organs to shrink, and damages immunity by shrinking the thymus gland. It is the hormone of darkness and winter, and is produced in the pineal gland by any stress which increases adrenalin. Adequate sun light suppresses the formation of melatonin.

This means that the immune system is most responsive in the summer, when days are long. Daylight stops the stress reaction, and protects our immune system.

Q: Doesn't exposure to the sun age you?

This effect is variable, and depends on our hormones and diet.

The unsaturated oils have been identified as a major factor in skin aging. For example, two groups of rabbits were fed diets containing either corn oil or coconut oil, and their backs were shaved, so sunlight could fall directly onto their skin. The animals that ate corn oil developed prematurely wrinkled skin, while the animals that ate coconut oil didn't show any harm from the sun exposure. In a study at the University of California, photographs of two groups of people were selected, pairing people of the same age, one who had eaten an unsaturated fat rich diet, the other who had eaten a diet low in unsaturated fats. A panel of judges was asked to sort them by their apparent ages, and the subjects who consumed larger amounts of the unsaturated oils were consistently judged to be older than those who ate less, showing the same age-accelerating effects of the unsaturated oils that were demonstrated by the rabbit experiments.

While it is important to avoid overexposure to ultraviolet light, the skin damage that we identify with aging is largely a product of our diet.

Q: Don't you have to avoid sunlight because of skin cancer?

The type of skin cancer which is clearly caused by sunlight is a relatively harmless type of cancer, which appears only in sun-damaged skin. Melanoma, which is often called a skin cancer, because it sometimes begins in moles, does not have such a simple relationship to sunlight, and its incidence is significantly increased by the use of estrogen.

It is often said that the great increase in deaths from melanoma during the last 60 years has been caused by an increased popularity of sunbathing, but during the same time there has been a great increase in the incidence of cancer of the prostate, which is in a location that gets very little exposure to light. What these two cancers have in common is a sensitivity to estrogen, and it is during this same period of time that we have been exposed to increased amounts of estrogen-like chemicals

in the environment as a result of industrial pollution: Dioxins, phenols, chlorinated hydrocarbons, DDT, smoke, etc. It is likely that these cancers (and others) are caused by the estrogenic pollutants.

The incidence of melanoma is consistently lower at greater elevations, where ultraviolet light is more intense, than at lower elevations. It is common for melanoma to develop on relatively shaded areas, including the middle of the back and the inside of the thigh, unlike the ordinary less malignant skin cancers, which develop most often on the forehead, nose, ear, cheek, and lip, where sun exposure is greatest. People who work outside have a low incidence of melanoma according to some studies, and this is sometimes said to be because they don't get sunburned, as pale people do when they spend time in the sun after being indoors for long periods. Sunburn does cause freckling, which is a clumping of pigment cells, but recent studies show that children who get sunburned are not at increased risk for melanoma. Sunburn causes complex changes in the tissue, including weakened immunity.

To avoid the aging and immuno- suppressive side effects of sunlight, it seems best for sunlight to come through a window glass which removes most of the ultraviolet light, and some of the blue light. Plastic film is available which contains copper that removes this harmful part of sunlight, and can be applied to ordinary window glass. Sitting in sunlight coming through a window of this sort, for short times during the day, is very protective. Besides protecting against cancer, it helps to keep the mood and energy level high, by keeping melatonin low and stimulating metabolism.

Recently, the polyunsaturated oils have been identified as the main thing in cells that radiation interacts with, to cause cellular damage. Vitamin E, taken internally or even applied to the skin, has been found to reduce the damage produced by exposure to ultraviolet radiation, which is logical, since it interrupts the chain reactions of toxic free-radicals produced when unsaturated oils are oxidized by radiation or other injury. Aspirin has been found to have a similar effect in reducing the harmful effects which develop in the skin after sunlight overexposure. Coconut oil has been used for generations in "suntan lotions," and whether it is absorbed through the skin or eaten as a food, it clearly has a protective antioxidant function. Carotene seems to work with vitamin E in the skin to reduce injury by ultraviolet radiation.

Caffeine also has shown a protective action against radiation, but its mechanism of action isn't clearly understood.

Q: Why not use sun-blockers, so you can get light without getting burned?

If a sunscreen lotion is based on the use of an opaque reflective material, such as zinc oxide or titanium oxide, that substance remains mostly on the surface of the skin. This should make it fairly harmless, though it is possible that traces of titanium could be absorbed with oils into the skin, where it could be made toxic by interaction with ultraviolet rays.

However, other chemicals used in the sun screen lotions, such as PABA derivatives, also react dangerously with light, and are easily absorbed in significant quantities into the deeper layers of the skin, where they can cause mutations.

For example, several recent studies have found that the sun-blockers, which decrease the ordinary skin damage caused by ultraviolet rays, actually increase the risk of developing melanoma, by causing mutations when the cells' chromosomes interact with the sunscreen and the light. (Something similar happens in the disease, porphyria. A pigment that accumulates causes the skin to become very sensitive to the sun. Estrogen is known to intensify the disease.)

Even natural colored compounds, which have sometimes been used in suntan lotions, should be avoided, since they might be able to transmit the energy of light to the chromosomes, causing mutations. Radiation from the sun reacts with the unsaturated fats you have eaten to cause oxidative damage to skin cells. Vitamin E, vitamin A and carotene are antioxidants that prevent skin cell damage, when they are taken internally or applied to the surface of the skin. None of these causes any harmful effects in the sun.

Aspirin reduces the iron content of the blood serum, and also inhibits the formation of the sometimes-toxic prostaglandins from fatty acids. Coconut oil is very resistant to radiation damage and, like vitamin E, tends to stop the chain reactions that occur in unsaturated fats. The old formula for suntan oil, coconut oil with iodine, might turn out to be a safe sunscreen, since the brown iodine absorbs light, as other "U.V. blockers" do, but iodine is also an effective chain breaker that inactivates free

radicals, and it can't be absorbed into cells in its brown form. It doesn't have the potential for causing cancer that the popular sunscreens do.

Q: Is sunlight still beneficial if you use a safe sun blocker?

The popular chemical sun blockers are meant to stop the ultraviolet rays. If they can do that, without increasing the risk of melanoma, then they are very beneficial, because this will allow you to get a long exposure to direct sunlight, which penetrates deeply and has an anti-stress effect. But so far, there is no research that shows any of the chemical ultraviolet blockers is safe.

Q: Why do people seem to get sicker in the wintertime, often right after Christmas?

Nights are much longer in the winter, and even in the summer, death rates are higher during the night than in daytime. December 21 is the day with the fewest hours of sunlight, but the cumulative damage of prolonged darkness reaches its peak about a month later. Cold temperatures do have some harmful effects, but by keeping people indoors, or bundled up in thick clothing, cold weather also causes us to get very little exposure to sunlight. Winter sickness is mainly the result of a "light deficiency."

When young sailors spent 6 months in the continuous polar night of Antarctica, they developed the same signs of nocturnal stress that are common in old people during the night. Many old people habitually get up before dawn, because they find it impossible to stay asleep. Even healthy young people (and animals) experience some degree of nocturnal stress as soon as the light is turned off at night, and their body responds with an increased production of adrenalin and cortisol.

The energy-producing part of cells, the mitochondrion, shows signs of being increasingly damaged as the night progresses, but they are gradually restored to their normal condition during the daytime light hours. This means that our greatest ability to resist stress is in the late afternoon, and we are most susceptible to injury at dawn. In the winter, nights are long and days are short, so we experience a cumulative increase in our susceptibility to stress-injury during the winter months.

The light which penetrates deeply into our tissues (mainly orange and red light) is able to improve the efficiency of energy production' and to suppress the toxic free-radicals that are always being formed in cells.

Q: Can you get enough sunlight during the summer to hold you through the winter?

No, many of the beneficial effects of bright light disappear during just a few hours of darkness, though the restoration of our tissues that happens during the summer puts us into a better state for surviving the winter, for example by allowing massive regeneration of the thymus to occur. (This occurs in adults, not just in children. The idea that the thymus disappears after puberty is based on autopsies. If a person lives for even 3 hours after an accident or the onset of sickness, the thymus has had time to shrink.)

Frequent short exposures to bright light is almost as valuable as continuous sunlight, and it is less likely to cause skin aging.

Q: How much sunlight do we need a day for general health?

If artificial light is bright enough, it is as effective as sunlight at stopping the stress reaction, but people seldom use lights that are bright enough. Generally, people and animals are healthier when days are longer than 12 hours, that is, after March 21 and before September 20. When days are shorter than 12 hours, artificial lights should be used from sunset until bedtime, but the greatest brightness probably doesn't have to be continuous.

Studies on isolated organs and tissues suggest that a few seconds of penetrating bright light are enough to break the free radical chain reactions, slowing the production of toxic substances, which tend to increase in concentration during nocturnal stress. A few seconds' exposure to the direct light of ten 150 Watt incandescent bulbs, for just a few minutes every two or three hours, might provide more effective protection than continuous exposure to a single 100 Watt light.

Glossary

Mutations are changes in DNA molecules which can kill cells, or accelerate their aging, or contribute to the development of cancer. Cellular respiration: the ability of cells to consume oxygen and produce useful biological energy.

Free radicals are parts of molecules that can be produced by radiation (including sunlight), which contribute to cells' aging, cancer, and mutations.

The thymus gland is an essential part of our immune system, and it shrinks when we don't get enough light.

Melatonin, or pineal hormone: the pineal gland in the brain responds to an absence of light (or to any stress which increases the adrenalin systems) by secreting a hormone called melatonin, which lightens the skin, makes the brain sluggish, turns off thyroid and progesterone production, and suppresses immunity and fertility.

Immunosuppression refers to any process that lowers the efficiency of our immune system, such as stress, radiation, or poisoning.

Summary

1. In fall and winter, use very bright incandescent lights daily from sunset until bedtime.

2. Expose as much skin as possible to the bright light; even a minute is better than nothing. Thin, light-colored clothing transmits a considerable amount of light.

3. Infrared bulbs, with clear glass, are especially beneficial. Special low temperature red lights are available.

4. It is better to get your sunlight through windows, because it has less ultraviolet light than direct sunlight.

5. Don't use sun-blocking lotions, other than the simply reflective type (zinc oxide or titanium oxide).

6. Decrease the use of unsaturated oils in the diet, and use coconut oil as food and also on the skin during exposure to direct sunlight.

7. Vitamin E and aspirin reduce the harmful effects of sunburn, even when used after exposure to the sun, they can be applied topically to the burned skin. Vitamin E often contains some soy oil, so I recommend small doses of about 100 mg per day.

Vitamin A Toxicity

Townsend Letter for Doctors, October, 1985

YOU printed a letter to the editor regarding vitamin A; I've been tracking down vitamin A scare stories for years, and when I wrote to the researcher mentioned, he denied working on vitamin A.

In 1974 there was a well circulated rumor, in Washington and Oregon, that vitamin A had caused blindness. I traced the story to a professor at the University of Oregon Medical School, but she refused to talk to me about it.

I think the symptoms associated with moderate amounts of vitamin A in susceptible people are the result of temporary suppression of thyroid function, which can result from an excess of any unsaturated oil. Vitamin E, which spares vitamin A, has a powerful effect in preventing toxicity from large doses of vitamin A. In traditional diets, people who ate fish livers also ate fish thyroids.

The three big dangers in the U.S. diet are iron supplementation, excess of unsaturated oils, and sodium restriction. If you would like a review of research on these dangers, I would be glad to write it up.

Response to "A New Look at the Meaning of Reality"

Science News, Volume 99, Number 26, June, 1971

YOUR article, "A New Look at the Meaning of Reality,"[1] was interesting, but uninformed. Some criticisms: These ideas are not so new, at least when compared with what you call "traditional behaviorism." You seem to be trying to give the impression that these humanistic psychologists are emotional rebels against staid, sane and scientific traditionalists like Skinner, and that a theory is just now being created for them.

Kurt Goldstein (The Organism) apparently coined the phrase "self actualization," which was central to Maslow's very biological but also social psychology. Whitehead and the Gestalt psychologists showed several decades ago that consciousness shouldn't be thrown out of biology and psychology. Carl Rogers (e.g., *Client-Centered Therapy*, 1951) did very coherent theoretical as well as sound empirical work which led to the interest in group therapy and the awareness of the social implications of therapy. Merleau-Ponty and Michael Polanyi have provided very broad critiques of the pseudo-objectivity that Laing refers to.

Newspaper Excerpts

A la Carnegie

Eugene Register-Guard, November 15, 1984

THE Election Day announcement that the U.S. government is considering an invasion of Nicaragua was reported in the Wednesday *Register-Guard*,[†] which also editorially advised readers that "American compassion cannot prevent death through starvation…in famine-ridden countries…" yet pointed out that they could relieve their consciences by supporting soup-kitchen charities at home and abroad.

After your endorsement of Reagan, I suppose you feel the way Andrew Carnegie did when he said: "To continue much longer with most of my thoughts wholly upon the way to make more money in the shortest time, must degrade me beyond hope of permanent recovery."

Your editorial reaction is classical. Harming people who are attempting to feed themselves, and then publicly advocating "charity."

Two hundred years ago, such deceit was understood by honest people. William Blake wrote: "Pity would be nor more if we did not make somebody poor."

The charitable Carnegie Foundation was a pioneer in attempts to eliminate poverty by eliminating the poor. Their theory was that poverty was genetic. What is your theory of poverty? And why do you believe American compassion couldn't eliminate starvation?

If compassion consisted of withdrawing military support from brutal dictatorships around the world, people could begin to feed themselves.

It is no threat to me that Nicaraguans are learning to read and to cooperate with each other in overcoming poverty. Unfortunately, it seems to threaten Reagan and his supporters.

Almost Anyone

Eugene Register-Guard, October 15, 1976

PRO-NUCLEAR scientists, especially when their income depends on it, can behave oddly. In the 1950s, the program that measured bomb fallout was named "Project Sunshine," and some government scientists even claimed that fallout was good for us, "because radiation produced evolution." At least, they assured us,

[†] "Millions Are Starving," *Eugene Register-Guard*, November 7, 1984.

a little radiation wasn't harmful. Some "experts" still claim that the Hiroshima bomb didn't cause measurable genetic harm, but to reach this conclusion, people who were upwind from the explosion have to be averaged in.

The experts in nuclear energy often find it profitable to disregard the public's safety. More than 60,000 drums of radioactive waste were dumped in the ocean near the U.S. coasts, and after years of such disposal, divers investigated and found the barrels had been crushed by pressure, allowing the radioactive material to escape. Could this be considered "accidental" pollution? According to "Industrial Research," nuclear accidents have been increasing recently; however, much pollution is "permissible," rather than accidental. One government plant measures its daily emissions in terms of pounds of uranium.

Establishment physicists claim that their knowledge is complete enough to prevent miscalculations, but a State Department official has pointed out that nuclear test blasts have been unpredictable in size. Anderson and Spangler have presented evidence which contradicts the basic assumption on which nuclear reaction rates are calculated.

Everyone in the world is going to be involved in the outcome of our nuclear energy decisions, and the way many physicists are acting, almost anyone's opinion seems more reliable.

Bad Partnership

Eugene Register-Guard, March 30, 1985

YOUR article[†] discussing a conspiracy to promote the use of poison sprays, illuminates a more general problem. There is a trend toward a kind of partnership between some big universities and corporations which use new technologies; the people involved assure us that this trend will benefit the public—the consumers—but there is a good reason to doubt their objectivity and their correctness.

A Central California farmer who changed from chemical to organic methods, and now sells most of his products competitively to the ordinary supermarkets, has pointed out that the state universities which have spent so much public money to promote the agricultural methods favored by the chemical industry had absolutely no information to offer him to help in his conversion to completely natural methods. By eliminating the use of expensive chemicals, he saved enough to compete effectively in

[†] Bill Bishop, "State Accused of 'Spray Scam'," *Eugene Register-Guard*, March 15, 1985.

the market, in spite of the large research establishment which works closely with his competitors.

How much more cheaply could he produce food if he could have the advantage of research financed largely by the public?

If the state universities act as agents of the chemical industry, should they receive public money? Public finance should function as a counter-balance to the private money which buys the research it wants. Entire institutions can be swayed by the financial leverage of their "patrons."

When professors, who are agents of the state, accept any research funds from private industry, and then participate in any government decision which affects the profits of that industry, it certainly doesn't look good…

Ban Lead

Eugene Register-Guard, July 13, 1977

LEAD pollution can cause mental retardation, hyperkinetic behavior disorders, anemia, bone disease, and accelerated aging and degeneration of various tissues. Children are most vulnerable to lead poisoning. Leaded gasoline is the main source of lead pollution.

Some cities have banned the use of lead in gasoline. Why hasn't Eugene?

Dangerous Therapy

Eugene Register-Guard, May 23, 1985

I hope that the kind of information Sarah Stewart provides in her long reply to Mr. Frank's letter[†] is not the kind of information that doctors give to patients in obtaining their "informed consent."

In such drastic and permanent "therapies" as electroconvulsion and "leukotomy" or "psychosurgery," practically no properly controlled studies have been done. In one controlled study, the electrodes were applied to the patients' legs, instead of to the head, and the beneficial effects were just as good—and the risk of brain damage was obviously less. Physicians are careful to warn the public of the need for controlled studies before therapies using natural substances can be accepted; shouldn't removal of part of the brain have an equivalent scientific evaluation? The judgment of the person who administers the treatment is often accepted in evaluating "psychosurgery."

The machines for administering electroshock were required by

[†] Sarah Stewart, "Mental Health Care has Improved," *Eugene Register-Guard*, May 17, 1985.

law to be evaluated by the FDA. It placed them in the highest risk category, based on health risks including brain damage. By law, devices in that category were to be removed from the market if investigation didn't establish their safety. They remain in that category, but the FDA has not acted, as the law would seem to require.

The regulatory agencies are now acting flagrantly for the benefit of the big economic interests, and against the interests of the consumers. It would be nice if we could return to the rule of law.

Find the Facts

Eugene Register-Guard, June 24, 1977

IF fluoridation proponents have such a high regard for the public that they will prescribe and administer mass medication for them, and such a high estimation of the public intelligence that they believe medical and dental issues should be resolved by a public vote, then it would seem that they should have enough respect for the public intelligence to participate in some form of a public debate or at least a presentation of the actual facts in support of their position.

Since it seems that no proponent is willing to come right out and cite the particular scientific publications which support their position, and since it seems that there is no dentist or physician in this area who is willing to defend fluoridation in a public debate, and since Eugene magazine has already published enough information to make many people question the scientific competence of the fluoridation proponents, isn't it the responsibility of the *Register-Guard* to present a detailed discussion of the evidence which is claimed to demonstrate the efficacy and safety of fluoridation?

If the proponents resort to the argument that our small (public) minds couldn't understand and evaluate such scientific issues, then they are asking the public to accept their "professional authority." It might take some work to find and analyze the facts in support of fluoridation, the facts which are vaguely referred to by the advocates of fluoridation, but I think the public deserves a chance to see, in the Register-Guard, the facts on which the health professionals are basing their "authoritative" judgments.

† Allan Winkler, "History of the Atom Bomb Does not Explain its Initial Use," *Eugene Register-Guard*, July 22, 1982.

German Connection

Eugene Register-Guard, July 28, 1982

Allan Winkler's article† on Truman's use of the atomic bomb against Japan devotes some space to the question of whether U.S. policy toward the Soviet Union significantly influenced Truman's decision to incinerate several hundred thousand civilians. Before drawing his conclusion, I think he should have mentioned that Truman was known to be so anti-Soviet that he advocated supporting Hitler in his attempt to destroy the Soviet Union, and that the big-city Democratic party bosses, who were instrumental in getting Truman the 1944 nomination, and the presidency, also favored Hitler. Roosevelt and Vice President Wallace were working to insure good post-war relations between the U.S. and the Soviet Union, and this was known to be a major reason for dumping Wallace and choosing Truman. The maneuvering was so obvious that Stalin believed Roosevelt was assassinated to implement the new policy at a crucial time.

With the recent revelations of the secret importation of large numbers of fascist war criminals into this country, and the German connections of people who became prominent in our Cold War government (such as the Dulles brothers), Winkler's presentation of the context for the first use of the atomic bomb really seems inadequate.

Gossip Unfounded

Oregon Daily Emerald, December 15, 1975

I was asked by the assistant director of the SEARCH program to help with the organization and teaching of a class in nutrition. The student who was helping to get a department's approval encountered the explanation from a department source that I would not be allowed to teach it because I advocated "Adelle Davis' ideas." He said that they "know where" I "get my information." As far as I know, I have never talked to anyone from that department, so they could have no proper basis for knowing where my information "comes from." (Much of my information does come from an underground source, the subterranean science library at the University of Oregon.)

The fact is that I have never "taught Adelle Davis' ideas," and have rarely mentioned her books in a class, because I disagree with some of her emphasis, and feel that her books are not organized in a way that would make them easy to use in a class. However, I consider her to have been infinitely more

respectable than the envious nutritionists who have called her a quack.

This kind of unfounded gossip may be normal academic ethics at the University of Oregon, but I have no reason to tolerate the dissemination of misinformation about myself (or about Adelle Davis or Linus Pauling or Rodger Williams), so I am requesting that those statements either be retracted or defended in a public forum.

Since I was accused of teaching things that were "not true," I think the accuser has the obligation of meeting me in a public debate on those issues, or of admitting his error.

Health Frauds

Eugene Register-Guard, November 16, 1985

THE recent article[†] about the National Council Against Health Fraud might raise a person's suspicions, because of the freakish and probably trivial nature of the frauds mentioned. The immense problems they failed to mention suggest that they might be acting as a front for the drug industry.

Legal drugs for arthritis and cancer are worth several billion dollars annually. We are often told that more and more people are being cured of cancer each year, yet each year the cancer death rate increases. Is deception involved?...

The most extensively used and advertised "health food" is liquid vegetable oil; there has never been evidence that polyunsaturated oils improve anyone's health, beyond the trace amounts required as essential nutrients, and there is very clear evidence that large amounts are profoundly toxic. Is the huge food oil industry engaged in a dangerous health fraud?

In recent years clear evidence has emerged implicating supplemental iron in carcinogenesis. Do the drug companies who promote iron supplements warn the public about the danger of leukemia and other cancers? Does their advertising constitute a dangerous and deceptive health practice?

If a major drug for treating asthma contains metabisulfite, known to kill some people with asthma, should the public be warned? When a major medical journal, getting money for advertising the product, refuses to print a letter warning of the danger, is the health fraud council willing to investigate?

[†] Bill Bishop, "Oregonians Form Group to Combat Health Fraud," *Eugene Register-Guard*, November 5, 1985.

Undoubtedly the algae dealers are easier, more entertaining targets, but the absence of all of the biggest health deceptions from their list seems to say something about the group's real purpose.

Humanities Stifled

Eugene Register-Guard, April 13, 1982

Fred Crafts' article[†] reports that the Committee on Arts and Humanities intends to establish better relations between campus and city and to improve their promotion and marketing of the humanities.

The boring sameness of viewpoint which we find in the academic humanities is not because the subjects have some intrinsic lack of "momentum," as suggested in the article. The humanities are potentially so important, so exciting, so disruptive, that they have been deliberately stifled…

If the "humanities" are to be revived, it will not be by giving lectures to Rotary clubs. It will be because the "humanists" begin to take positions of human significance. Opposition to plans for nuclear war, opposition to militarism itself, opposition to oppressive legislation such as SB 1630, opposition to policies which impoverish millions of people, opposition to policies which make higher education impossible for a large part of the population, opposition to academic policies which allow tens of millions of people to become so gullible that they can be victimized by economic theories that were already discredited more than 50 years ago—these are positions which should grow naturally out of the humanities. If the universities take credit for intellectual achievement, they have to take blame for the production of a gullible generation. If the "humanists" start acting like human beings who are imbued with the great values of humanity, and begin criticizing, thinking, and imagining, instead of conforming, then the humanities can be revived.

Ill-Informed Statement

Eugene Register-Guard, February 21, 1991

I hope someone at Pope & Talbot Inc. is embarassed when they realize that the statement on dioxins they authorized Dr. Robert Loomis to make on their behalf[‡] is not only impolite and misleading (which

[†] Fred Craft, "Bringing Revival to the Humanities," *Eugene Register-Guard*, April 1, 1982.

[‡] Robert Loomis, "Activists in a Hurry to Eliminate Dioxin," *Eugene Register-Guard*, February 14, 1991.

might have been their intention) but also so ill-informed that he is probably going to feel obligated to retract parts of it.

If a student of mine had submitted that composition to me, I would have returned it ungraded for reconsideration and revision. If I were associated with Pacific Hospital Association, I would want to check Loomis' background in chemistry, epidemiology and toxicology. I suspect that many high school students are going to be submitting their detailed refutations of the physician's statement.

Impact Unknown

Eugene Register-Guard, April 27, 1988

ACCORDING to your recent article,[†] the cheif of the U.S. Forest Service says he doesn't know what ancient trees are. Many people would acknowledge that we really don't know very much about the ancient trees and how they related to the world around them, but almost any educated person would believe it is not proper to destroy something which you don't understand. Foresters are not educated to serve the interests of humanity in general, or to work for the good of our biosphere, or even for the U.S. national interest; rather, they are trained to serve the interests of the corporations which use trees.

The true environmental impact of cutting ancient trees is not fully known, and can't be known until better research is done. It would be reasonable to have a moratorium on cutting ancient forests, while research continues.

Forests of ancient trees are the greatest concentration of biomass anywhere on Earth. An ancient forest often has 100 times more biomass than a "young and productive" forest. The forest biomass is not inert, like a coal deposit, but contains a large quantity of exchangeable water, which allows a forest of giant trees to stabalize humidity, temperature, and even percipitation and climate in general. In areas which have long recorded history, it is clear that deforestation has greatly increased the frequency of droughts. Oregon and California are now beginning to experience what has happened earlier in other areas, including Africa, India, and Russia. The same destablization which produces droughts can also increase the frequency and intensity of flooding.

Taking short-term profits at the expense of long-range viability should no longer be an option. We

[†] *The Associated Press*, "Forest Service Chief Asked: 'Are You Stealing Our Heritage?'," *Eugene Register-Guard*, April 15, 1988.

need new public institutions with a broader view of the stewardship of resources.

Irresponsible Appeal

Oregon Daily Emerald, April 16, 1975

SINCE Senator Morse always seemed to know more of the important facts than the rest of Congress put together, Horn's foolish comment in the fund-raising letter[†] shows the extent to which a "non-political" university can go in trying to sell itself to the presumably reactionary prosperous alumni. Some alumni would prefer more responsible, literate appeals.

Look to the Future

Eugene Register-Guard, August 24, 1986

IN a historic human rights declaration, the United States pledged that all of its citizens had a right to a job, even if the government had to provide the jobs. Though it is common for the government to ignore pledges, contracts, laws, etc., economic realities still gice a kind of sanctity to the idea of full employment.

The recent discussions of "jobs vs. owls" often hinge on the fact of the desperate importance of jobs in a society which fails to provide decent opportunities for employment.

Another way to frame the same issue would be "unprecendented concentrations of wealth and power in the hands of the richest 0.5 %" vs. "preservation of enough of the natural biological world that regional or planetary systems do not go into irreversible decline."

The people who destroyed the coastal forests of Chile and created the Atacama desert didn't have the information with which to imagine the consequences of their actions. The people who removed the forests of Mexico's high plateau earlier in this century were foreigners whose grandchildren wouldn't have to see the barren, erroden, uninhabitable regions they created. But resident Oregonians, even if they are heirs to the multimillion-dollar fortunes made by the removal of Oregon's forests, should begin to develop their imaginations and consider what their grandchildren will think of their inheritances.

Maybe they could begin to imaginatively construct a future in which people have a right to jobs which do not degrade the physical, biological, social, and cultural environments.

[†] Alan Maltun, "Libeling the Dead," *Oregon Daily Emerald*, April 7, 1975.

Missed Point

Eugene Register-Guard, January 12, 1978

YOUR editorial on Robert Wright[†] seems to have missed the point he has repeatedly made in his letters; the bar, even more than the other professions, is established, in teh same sense that religion used to be established.

You say that "he hasn't passed the test that proves" he is well trained in law. Since you say that the courts have "properly limited his activities," "unless and until he does" pass the test, you seem to be saying that he has a right to take the test. Are you willing to say that openly? If not, I think that you are deliberately trying to confuse any reader who may not know that a person has to be "qualified" to take the test by having a law degree. (Since you refer to Wright as "self-trained" I assume he doesn't have a law degree.)

Professional schools are places of socialization and indoctrination. How many communists graduated from professional schools during the McCarthy era? How many disestablishmentarians, such as Wright, are allowed to enter Oregon's schools of law? Professions have value systems and ideologies built into them. Tests can in fact measure mere competency, but they are not very good at selecting individuals who have the proper values.

If tests "prove" the quality of training, as your editorial indicates, then Wright should be allowed to take the test, and to enter the bar if he passes it.

Do you disagree?

Money or Morality?

Eugene Register-Guard, July 25, 1985

PEOPLE working on the "Riverfront Park" project realize that military research might be done there, but claim that this is not an appropriate area for political or moral concerns. Richard Hersh, former university vice president for research said[‡] that it was an "oversight" that the project's directors were selected without a public announcement, and that "it never entered" his mind that the board is politically biased; but he admitted believing that Democrats are not "successful in business in this town."

According to the *Register-Guard*,[§] university administrators oppose extending the ban on clas-

[†] "The Wright Decision," *Eugene Register-Guard*, January 5, 1978.
[‡] Jim Boyd, "Science Park process is Criticized," *Eugene Register-Guard*, May 18, 1985.
[§] Lisa Strycker, "Strict Limit to Research is Rejected," *Eugene Register-Guard*, July 19, 1985.

sified research to the Riverfront Research Park: They are "reluctant to impose morals on a commercial enterprise." The vice president for research, John Moseley, says "there would not be a Riverfront Park" without classified research.

Forty years ago, many of the people who worked on the Manhattan Project realized that weapons-related science has a moral aspect. Hans Bethe, for example, now actively opposes the Strategic Defense Initiative, which is designed to give the illusion that the bombs can be used without fear of retaliation. The moral and political questions involved in secrets weapons or "defense" research are now clearer than they were when work was begun to produce the first nuclear bomb.

Our universities have always found it easier to work in the interests of big corporations than to support the interests of workers and ordinary people, because even state funds are influenced by business people. but when it openly becomes a choice between money and morality, President Olum should boldly take a stand against prostitution of the university.

Not Generous

Oregon Daily Emerald, January 22, 1973

THE aspect of Mailer that you condemn is what's best in him.[†]

You apparently have evidence that "good fucks" don't "make good babies," since you saved your wildest insults for that "pseudo-biological hypothesis" of Mailer's.

Before you can convincingly reject this and other sexual-political ideas of Mailer's, you should be able to dispose of the following observations, which have reported in recent years in medical, biological, and psychological journals:

Circulatory patterns are not the same in women who have a capacity for pleasure and orgasms, and those who don't.

Schizophrenia has autonomic and circulatory correlates.

Women who are schizophrenic at the time of conception abort male embryos much more than female embryos, and if their symptoms appear late, male babies are more likely to have defects: male embryos are known to be more sensitive to a variety of unhealthy uterine conditions.

Bad uterine conditions can cause defective babies, including small brains and mental retarda-

[†] (Regarding Barry Mitzman's comments on Mailer's "Catholicism.")
Barry Mitzman, "Mailer Converts—Almost," *Oregon Daily Emerald*, January 12, 1973.

tion, depending on when the trouble occurs, what it is, etc.

Improved uterine conditions—presumably the circulation—can improve the percentage of healthy and precocious babies.

The literature that may be relevant to this question is surprisingly large and varied—surprising, because our culture is ruled by an anti-biological dogma that denies any connection between physiology, emotion, and politics.

Your commitment to an abstract, anti-biological form of existentialism is fine for a bourgeois literary critic, but to imply that such a philosophy is the best hope for women is not very generous.

Nuclear Blackmail

Eugene Register-Guard, August 19, 1981

THE interior secretary's vision of our natural resources being consumed by the big corporations before Armageddon, and the Pentagon's increasing preparations for nuclear war, on the surface might suggest that this is a terminal administration, really preparing to wind things up forever. While it is true that some of our leaders lack common sense, I think their advisers and promoters have more "realistic" plans for the future.

The neutron bomb is not popular in Mexico. Many people realize that it would be a handy weapon to be used by a neighbor intent on invading and occupying their oil fields. If affairs don't go well for the U.S. in the Middle East, I think our policymakers will apply all necessary pressure to get as much oil as needed at a favorable price from Mexico. While the weapon could easily trigger nuclear war if used in Europe or Iran, I believe some policymakers would feel that it could be used in this hemisphere without threat of nuclear retaliation. For some Mexicans, deployment of that weapon in the U.S. constitutes nuclear blackmail and terrorism.

It is not in our interest to allow the neutron bomb to become another tool of the oil corporations.

Other Factors

Eugene Register-Guard, Novemeber 4, 1980

YOUR editorial[†] on declining scores on the Scholastic Aptitude Tests considered only educational and social factors as possibel causes. At a recent conference of military psychologists concerned about the mental quality of their recruits, I learned that some of them believe that the actual biological intelligence of Americans is dete-

[†] "SAT-Score Depression Persists," *Eugene Register-Guard*, October 24, 1980.

riorating because if factors such as malnutrition, food additives, and effects of the estrogen in birth control pills.

Estrogen excess in pregnancy, like a thyroid deficiency, has been known to damage the growing brain.

A study of nutrition in San Diego showed that 10% or more of the people born in that area are below the nutritional level at which brain damage is to be expected.

Shanklin and Hodin (in *Maternal Nutrition and Child Health*) have documented that medical practices which became widespread in the 1950s damage the brains of large numbers of babies.

Last year the government advised against the use of soy in baby "formulas," shortly after it was discovered that such vegetable oils can cause brain damage.

Because of the political and financial implications of these facts, many people are reluctant to discuss them publicly. I hope your next editorial on declining SAT scores will include among the possible causes "istrogenic and dietary brain damage during pregnancy and infancy."

Paid-off Press?

Eugene Register-Guard, January 17, 1979

YOUR editorial[†] hesitantly admits the plausability of Dorman's and Omeed's interpretation of the performance of the U.S. press in reporting events in Iran.

As I read the daily falsehoods in the *Associated Press* reports about the shah's opponents, I tried to imagine how and where such views might originate. One theory that has been proposed is that Christian reporters were blinded by religious prejudace. Another theory is that they were just lazy, and got their news only from the shah.

Several weeks ago, a long and apparently honest interview with Khomeini was broadcast by our public television network, but the false reports continued to be printed in U.S. papers. Khomeini said the U.S. was forcing Iran to spend its money on American weapons, preventing real economic development in Iran. This was interesting and important news, but as far as I can tell, it never became "news" in the U.S.

It was at that point that a third hypothesis occured to me: Maybe the *Associated Press* people in Iran are working for the CIA or the USIA. As you undoubtedly know,

[†] "Did the Press Miss the Boat in Iran?," *Eugene Register-Guard*, January 12, 1979.

the CIA has in the pas used reporters and editors, both at home and abroad, to plant "news" stories. (Wasn't it a president of the American Society of Newspaper Editors who said that CIA payoffs had brought shame onto the press?) According to a University of California professor, the shah has continually "paid off" large segments of the American media (with checks, copies of which were published). The CIA could find less embarrassing ways to adminster the funds. To protect many billions in oil sales to the U.S., and weapons sales to Iran, suppose $1 billion was diverted to the media: a thousand payoffs of $1 million each. Much less would do, I suppose…

Policy, or Myth?

Eugene Register-Guard, April 12, 1984

WHILE I was visiting friends recently, their 11-year-old son told me he favored Reagan's reelection, because of his "realism" in spending more on the military, and less on social services.

I asked why that was "realistic," and the child and his parents answered that the Soviets would invade us if we didn't have a strong military. I asked why they thought that, and they said, in unison, "That's their stated policy."

Since then, I have heard that idea repeatedly: "It's their stated policy," to invade us, etc.

I have tried to find when such a policy was stated, but haven't found anything in the history of Soviet foreign policy except statements in favor of peaceful coexistance and universal disarmament.

If there is, or has been, such a policy, it is of the interest that people like me are unable to find it. If there has been no such policy, then it is of great interest, socially and politically, that so many people believe in a myth.

It seems that we have two types of people; those who feel desperately threatened by the Soviet Union, and those who don't. I think this indicates that the mass media aren't doing a good job in presenting background information on current topics, such as the arms limitation talks. If U.S. foreign policy is based on a paranoid myth, even newspaper publishers ought to be worried.

Poor Leadership

Eugene Register-Guard, May 19, 1981

WHEN half the people are functionally illiterate, traditional and simplistic opinions have a natural tendency to flourish.

A self-interested politician will know how to tak eadvantage of the public's cultural backwardness.

When a state superintendent of schools acts like a common politician, our culture is sure to be degraded.

When Verne Duncan says[†] that he would prefer leaving to local school districts the issue of equal time for creationism in the science curriculum, I feel he is providing retrograde leadership. If a state superintendent of schools can't inform himself and take appropriate action on a matter of curriculum, what is his function?

Power Misplaced

Eugene Register-Guard, April 18, 1985

It's hard to understand how Congress, which was constitutionally given the responsibility for deciding when to declare war, can allow one man to launch the missles which could end the world. Especially when the man with this power is one who plans to honor the dead Nazi soldiers while ignoring their genocide, and who has forgotten even which World War he is talking about: According to columnist Ellen Goodman, he said, "I felt since the German people have very few alive that remember even the war and certainly none of them who were adults and participating in any way..."

I doubt that such a mentatlity would even be allowed to renew his driver's license in Oregon, but in the White House he is allowed access to the Doomsday button.

Program Not Experiment

Oregon Daily Emerald, February 18, 1969

A system of "free scholars" has existed in England for 700 years. The basis of an Oxford education is reading, with comprehensive examinations required after the residence period.

Oregon's new program for 20 students is a very small step in the right direction, but to call it "experimental" seems to insult the other 14,000 students who will not be admitted to the program, implying that it is dubious that even 20 students are really motivated by a desire to learn.

Granted that some of the University residents need custodial care, it is improper to attempt to combine the functions of discovery and learning with the confinement and entertainment of socially irresponsible people.

[†] Teresa Barker, "Board Lays Creationism to Rest," *Eugene Register-Guard*, May 12, 1981.

I propose, therefore, that Oregon State, or a similar institution, be given a purely custodial role, retaining all the authoritarian features of the German universities we have copied in the U.S. for 200 years (including grades and examinations every few weeks.) This would free the University to be a university, in which every student was expected to be a free scholar.

Psychedelic

Oregon Daily Emerald, March 8, 1973

TIM Leary stands up for human rights and human desires. He's in prison, and may not get out in the 20th century.

Richard Alpert, of the New Haven Railroad family, is free to travel anywhere in the capitalist world, spreading the old ruling-class lie that desire is bad for you, that simple, thoughtless, passive labor is a proper human role.

Alpert is the opiate of the hippies. By comparison, Tim Leary is psychedelic.

Racism and Ideology

Eugene Register-Guard, October 27, 1983

MARTIN Luther King gave increasing attention to opposing the Vietnam War in the months before his death. He was teaching the public that militarism, racism and poverty are interrelated. Many conservatives hated him for making such connections, and asserted that he was taking a "communist" position. Hundreds of editorial writers advised him to stick to the issue of race, arguing that to tie it to the then-popular war would hurt his cause.

Racism is an ideological issue. Your editorial writer says, "He wasn't fighting political ideologies, he was fighting racism." Reducing racism to a personal, non-political question is to obscure the truth, that racism has been, and continues to be, used as an ideological weapon to keep people divided, poor, and helpless.

When King was killed, he was supporting a garbage workers' strike. He urged unity in the struggle against poverty and the war. The issue of unity is so important that people like Senator Helms, Govenor Thomson, and Reagan try to cover it up. I hope the *Register-Guard* writer simply forgot the historical facts, and isn't deliberately contributing to the effort to counteract King's work.

SAT Misconceptions

Eugene Register-Guard, May 20, 1986

THE decline in SAT scores, and the tests themselves, are of less importance than the ideological conflicts they reveal. Your recent

editorial publicized only one side of the argument.

To explain the changes in terms of a new type of student in the high schools, and the response of teh schools to this new population, threatens to be used as an argument for elitist educational programs, and for a lower class education for the "poor class of students."

Accounting for the change in scores on the basis of inceraased numbers of poor students taking the tests doesn't account for the fact that the shaprest decline occured among the highest scorers. Several studies have looked for extrinsic causes—cultural or biological—to account for the changes. Related studies were done for the U.S. Navy, to account for the learning problems of their recruits. Some of these studies are pretty convincing scientifically, but they have not been well publicized, because they place the blame on various powerful institutions in out society, rather than on the poor segments of society—who, as the numbers show, are not where the biggest change has occured.

Stop the Fanatics

Eugene Register-Guard, August 22, 1984

In the 1950s, many high officials openly advocated a first-strike "preventive" war against the Soviet Union. Government documents made public in 1983 reveal that such a war was scheduled to begin in 1949, and was postponed when the Russians demonstrated that they too had nuclear weapons. Rescheduled for 1957, the plan was again changed when the Soviets produced the hydrogen bomb sooner than expected, and were not in the desired weak position.

Officials such as Dulles and Goldwater wanted the atomic bomb to be used even in Vietnam.

When he speaks seriously to religious groups, and when he jokes with his staff, our President reveals murderous and paranoid thoughts.

Seen in their historical context, those statements shock humanity. Seen against a background of increasingly militaristic anti-Soviet television programming, they appear to be part of a campaign to prepare the public for further "anti-communist" adventures against small nations, probably in Latin America.

When high officials can claim that Mexico is the center of subversion in this hemisphere, it is clear that our government is moving toward bigger things than just the invasion and permanent occupation of Grenada.

A landslide victory for Mondale might come in time to stop the fanatics.

Time to Recant

Eugene Register-Guard, July 23, 1984

THE editors of newspapers who endorse a candidate take upon themselves a responsibility for the outcome of his policies.

As a result of Reagan's policies, real production and the prosperity of most people hav edeclined. Oil prices are not to blame, because they have declined in this period. Other industrial countries moved ahead in these years.

The poorest and weakest people have suffered the most. According to Harvard's School of Public Health, infant deaths "skyrocketed" in Boston and other cities, rising 50 % in a single year of Reagan's administration—a rate of increase equaled only during famines and plagues, and never approached before in American history.

The promised balanced budget turned into more debt than had accumulated in all previous history.

The giant corporations have profited to an extent that is unique in history.

Those giant profits of the monopolies were nothing but a transfer of funds from most people—a mortgage—to a few people.

The wealth transferred in four years is a debt which will never be repaid. But newspapers and the editors who bear responsibility for Reagan's election in 1980 should gein now to make a small gesture to the country, recanting their endorsement.

Under U.S. Control

Eugene Register-Guard, August 2, 1983

IS it possible that our President has confused Central America with "Middle America," with Iowa? This could explain his statements about "our front yard." But it wouldn't explain his fabrication of stories about "outside aggression."

What we are seeing now in Central America is not an "East-West" competition, but rather the consequence of a radical shift in U.S. policy which occured in the spring of 1945.

Roosevelt's Good Neighbor Policy was moral and made economic sense for capitalist America. Roosevelt's administration saw both the Soviet Union and Latin America as "vast markets" to be developed.

With Roosevelt's death, his dream of world peace based on trade and on justice as he understood it was replaced by a different ideology. The new policy was shaped largely by John Foster

Dulles, who described himself as a "sadist" who "thirsts for confrontation" with the Soviets and with independence movements in Latin America.

In 1945, the phrase "under U.S. control" was reserved for private government memos. The present economic crisis is bringing that kind of thinking into the open.

A few historians (and eventually journalists) were instrumental in educating the U.S. public about the meaning and origin of the Indo-China war. Similar work must now be done regarding Latin America.

Voters Face Test

Eugene Register-Guard, October 15, 1988

America's journalists and teachers will soon have a chance to see how well they have informed the public, how well they have taught them to value democracy. There will be a sort of national quiz on November 8 to see whether the public can remember which candidate for president is the one who:

1) Said he would find a way to evade a Supreme Court ruling. 2) Denounced Medicare as "socialism." 3) Conspired to decieve a president-elect with distorted intelligence reports. 4) Had many opportunities to recieve information on criminal activities and treason in connection with his office, yet claims ignorance. 5) Advocates a presidency which is above the system of checks and balances. 6) Counts on the overwhelming support of extremist Orange County to win California and the presidency. 7) Doesn't talk about the national deficit, because he and his buddies are the creditors. 8) Praised Poland's union members, said Detroit could use Eastern European workers' skills, but despises America's unions. 9) Claims competence in intelligence, yet allowed fascists and anti-Semites to hold high positions in his campaign organization. 10) Called himself a Goldwater Republican and openly advocated use of atomic bombs in the Vietnam War.

Most of these items were casually reported in the *Register-Guard*, others in the *Los Angeles Times* and other major publications.

War Unpopular

Eugene Register-Guard, April 13, 1986

A few years ago, when Argentina was ruled by brutal mass murderers, they were active supporters of the Reagan-Contra war against Nicaragua. Now that democracy has returned to Argentina, that country agrees with every other democracy in Latin

America, and with practically every democracy in the world, that the United States should not expand the war in Central America by sending additional support to the Contras. Even dictatorships such as the Pinochet government of Chile are surprisingly reluctant to openly support Reagan's plan for a major war.

According to polls, most Americans ignore or reject the false information they are receiving from Reagan's propagandists regarding events in Central America, and also oppose enlarging the war.

Unfortunately, our U.S. Congress is humiliating itself, by allowing itself to be so evenly divided on the issue of interfering in Central America; allowing itself to be so easily manipulated by the pseudo-patriotic rhetoric coming from the White House and the State Department.

Which Revolution?

Eugene Register-Guard, May 30, 1983

ANTHONY Lewis commented recently on the "astonishing" and "coold-blooded" way in which the Reagan administration disregards laws. he mentions environmental law, the right to travel, and peacetime censorship as examples. I had been thinking more in terms of his unconstitutionally fighting undeclared wars and violating treaties, but I appreciated Lewis' comments anyway; there are so many examples, one column or one letter isn't sufficient even to name them.

Another journalist recently said it would be nice if Congress would "speak out." That was a good idea, too, but in fact some congressmen did speak out not long ago, and threatened to stop the illegal war in Nicaragua. But the President told them to go ahead, pass "irresponsible" laws if they wanted, but the fighting would go on.

A member of his Cabinet gave a speech which was described as a "call for revolution" against out government because it is controlled by "the religious left." On this point, I'm not clear—has the revolution against constitutional government already taken palce, or is it in progress? Is there more defiance of the Constitution and of Congress and of treaties still to come?

After speaking with Reagan recently, helen Caldicott wonders "if we can make it for the next year and a half until the 1984 elections without a nuclear war." Maybe that's why no one in Congress is talking about impeachment; maybe they are just holding their breath, not wanting to rile the President. Maybe we should all hold out breath until January 1985.

Political Science of Sciences

The Blake List, Volume 1999, Issue 11, February 26, 1999

MAYBE the political right, the Nazis, etc., are the only ones who take art seriously, and can see that it is political work of the most effective sort. Science, when it is approached in the same way, is Art and Politics, and participates in intellectual war.

Acadamic obtuseness has always made it possible to ignore ironic and dialectical language, so I suspect that Ralph Dumain's riddles won't ignite many mental fires.

> The wretched state of the Arts in this Country & in Europe originating
>
> in the Wretched State of Political Science which is the Science of Sciences
>
> Demands a firm & determinate conduct on the part of Artists
>
> to Resist the Contemptible Counter Arts
>
> ...Strength to form the golden armour of science
>
> For intellectual War The war of swords departed now
>
> Are not Religion & Politics the same thing? Brotherhood is religion.
>
> Good & Evil are Riches & Poverty, a Tree of Misery,
>
> propagating Generation and Death.
>
> A Poet a Painter a Musician an Architect:
>
> the Man Or Woman who is not one of these is not a Christian.
>
> The Unproductive Man is not a Christian, much less the Destroyer.

You must leave Fathers & Mothers & Houses & Lands

if they stand in the way of Art.

Prayer is the study of Art.

Praise is the Practice of Art.

Fasting &c., all relate to Art.

The outward Ceremony is Antichrist.

Without Unceasing Practice nothing can be done.

Practice is Art. If you leave off you are Lost.

Jesus & his Apostles & Disciples were all Artists.

Their Works were destroy'd by the Seven Angels

of the Seven Churches in Asia, Antichrist Science.

The Old & New Testaments are the Great Code of Art.

The Whole Business of Man Is The Arts, & All Things Common.

No Secresy in Art.

Christianity is Art & not Money. Money is its Curse.

From a previous post:

I don't think anybody is playing arbitrary games with definitions or willfully stretching the definition of the political beyond recognition. Notice your key word above, "working", (my emphasis added): the implication seems to be that working is acting, engaging in overt political activity, not writing. But Blake was a writer and artist, who took definite positions as a writer if not as an activist on issues of hunger, poverty, tyranny, imperialism, slavery, and much more besides. How you could

interpret this as indifferent to improvement of the human condition in the material world is beyond me.

This is where a productive discussion should begin, rather than end. I hope I am not remembering something different than you are, but what comes to mind is the question of Blake's attitude towards the literal: is the sun a flaming disc that looks like the size of a guinea or the heavenly host screeching holy holy holy? Such symbolic acts of defiance of material reality have yet to be properly analyzed by anyone on this list, including me, esp. in conjunction with some more down-to-earth statements such as "we eat little we drink less/this earth breeds not our happiness." There is an issue of psychological resistance to material conditions in the face of which one is powerless, but these gestures of psychological resistance, that come from real, material, palpable suffering and the will to endure, cannot be reduced to New Age suburbanite hippy-dippy drivel that changing your interpretation changes what's happening, tiptoeing through the tulips as if one gets a free ride to live in a fantasy world.

I would be interested to know whether the scholarly Blake literature addresses all these questions, because I've not seen any that has to date. Rather than continue explicating my own views, let me pose a series of riddles to advance the discussion onto the next level:

(1) How are we to analyze Blake's statements of resistance in defiance of material conditions?

(2) How are we to analyze the political claims of Blake's vague and symbolic descriptions of apocalyptic conditions which somehow result in redemption, the new Jerusalem, in the light of how social change takes place and was taking place in front of Blake's eyes?

(3) When Blake says it was a mistake for Jesus to get involved in politics, and otherwise excuse his own disengagements from the political realm (including the statement Tim cites about how an educated citizenry would be immune to tyranny, and the statement that creation burns up when people cease to behold it), what kind of claim is actually being made? Is Blake advocating that everybody is wasting their time trying to change the political, material conditions of their lives, or merely that prophets like Jesus and himself are ill-advised to get mixed up in potentially life-threatening political situations in which they cannot possibly win?

By pursuing questions such as these, which all follow a similar pattern, I think we can progress much further through this murky character of Blake; symbolic politics relates to material societal conditions.

Re: Biblical Sources and More

The Blake List, Volume 1999, Issue 17, March 4, 1999

In his time (as in the present time), terrible things were used as medications, and probably were more deadly than what they were supposed to cure. Paracelsus invented a magical approach to medicine, in which the official medical crap would be applied to the sword that made the wound, leaving the lucky patient unmedicated. When I used to teach naturopathic physicians, they generally didn't appreciate my suggestion that this principle could account for the relative success of homeopathy when compared with 20th century medicine.

The great biochemist, Albert Szent-Gyorgyi, used to observe that humor was closely allied with the perception of important truth. I think Blake's humor is generally under-appreciated.

From a previous post:

> Beyond being a mere "alchemist", am I wrong in thinking that Paracelsus could also be called a doctor and chemist, who rejected traditional education and medicine, anticipated homeopathy, had something to say about "miner's disease", and could be viewed as a pioneer in both chemical medicine as well as empirical psychological science?

Re: For Raymond Peat

The Blake List, Volume 1999, Issue 15, March 1, 1999

I think the ramifications of that insight are very far-reaching and important. It's hard for many intellectual types to see that whole idea-complexes, as well as particular words, can be "used" creatively or for oppression and manipulation.

> *From a previous post:*
>
> > And was Blake as much of a "Christian" as much as *used* the religion that his country-men and women understood, and which also happened to be conquering the world, for more subversive themes, himself?

The reason I jumped from Blake to Lenin is that I think Marx was only abstract and sketchy in the way he revealed the theological idealism hidden in the various philosophies, but Lenin in his notebooks prophetically and concretely showed the fallacies that were repeated endlessly in 20th century philosophies of science, positivism, language philosophy, etc. Either people don't read Lenin's philosophical work, or they are so trapped in their theologies of "pure science" and other abstract systems that they can't respond in any way to his powerful analysis. I think that's why people don't talk about Blake's highly analytical revelations of the philosophical self-contradictions of the big-shots, it's the deep neokantianism that rules the official mental life at present.

As a biologist, I think Blake "used" the images of "a world all alive" as a fiendishly clever way to by-pass the dogmatic abstractions that ruled philosophy then as now. I think this philosophical condition accounts for the horrifying oppression that "vitalism" and "Lamarckism" have suffered. With Vernadsky and Hoyle, et al., I am inclined to believe that at least in an abstract and general sense, the universe is alive, but the "use" that Blake made of that idea was, I think, possibly the most intelligent philosophical act ever.

Re: Organs of Perception

The Blake List, Volume 1999, Issue 17, March 4, 1999

SINCE I see Blake as one of the few people who saw clearly in the 18th century, I like to look for people in this century who worked constructively with the same themes. Maurice Merleau-Ponty's work with the phenomenology of perception, building on the work of people like Kurt Goldstein, elaborates in modern terms this distinction between passive and active seeing and knowing. From Blake's references and images, I have guessed that Swedenborg's scientific discoveries were being discussed by scientific dissenters in London in Blake's time. The ratio of Blake to Swedenborg would be somewhat equivalent to that of Merleau-Ponty to Sechenov.

From a previous post:

> The phenomenal world is called by Blake "generation" or the "natural," and what he calls "mental" (because it is related to experience by the mind) is what we would call spiritual. The former kind of world is perceived with the "organs of sense" or the "natural and bodily organs," the latter kind with the "imaginative and immortal organs" (DC: The Bard, from Gray K576). I believe that in order to follow Blake one has to take seriously the existence of these "imaginative and immortal organs." This places him squarely in the tradition of Boehme, Swedenborg, etc.
>
> In his tractate NNR(#2) his first statement is: "Man's perceptions are not bounded by organs of perception; he perceives more than sense (tho' ever so acute) can discover."
>
> When Blake says: "the outward Creation . . . is as the Dirt upon my feet, No part of Me" (VLJ), he does not deny its presence (he calls it a "hindrance," and says: "while we are in the world of Mortality we must Suffer" (VLJ)) - but simply emphasizes that he is directed towards the spiritual, which to him is the substantial life.
>
> When Swedenborg writes: "Appearances are the first Things from which the human Mind forms its Understanding, and it cannot shake them off but by an Investigation of the Cause, and if the Cause is very deep, it cannot investigate it, without keeping the Understanding some Time in spiritual Light ...," Blake makes the annotation: "This Man can do while in the body." Blake's outlook is based on this belief that man has the ability to discern more than his bodily senses allow.
>
> At the Creation, the originally infinite organs of man were "shrunk" (into "female space"), and will be expanded when redemption comes,

to again behold Infinity. Our senses can only perceive what they have been structured to perceive, or as Blake puts it: "If Perceptive Organs vary, Objects of Perception seem to vary."

In M26 he says: "Every Natural Effect has a Spiritual Cause."

Re: Organs of Perception

The Blake List, Volume 1999, Issue 17, March 4, 1999

AROUND 1860, Sechenov formulated in a detailed way the idea that the brain and consciousness operate on the basis of reflexes (though Swedenborg seems to have anticipated the whole idea of the cortex of the brain and its (nerve cell) elements as the seat of consciousness with its varied faculties; all apparently for overcoming the dualism of Descartes). And then Merleau-Ponty showed why we shouldn't even believe in the literal reality of reflexes. (P.K. Anokhin worked out the more detailed and modern reasons for rejecting the simplistic idea of "the reflex arc," almost literally expressing the idea that we see, actively, through the eyes, not passively "with" them.) In the Russian tradition, the active consciousness has been taken seriously, unlike those in the west, who with Eccles, have insisted on separating the body from the (soul or) mind. One of my professors of neurology, for example, used to sarcastically ask me which I was going to study, the brain or the mind; he thought Pavlov had rejected the thought that neurologists could study the mind.

From a previous post:

> The ratio of Blake to Swedenborg would be somewhat equivalent to that of Merleau-Ponty to Sechenov.
>
> This makes me interested in looking into Merleau-Ponty, whom I have not read. Perhaps you could identify Sechenov for those of us unfamiliar with his name.

Re: Tim's Definition

The Blake List, Volume 1999, Issue 15, March 1, 1999

I don't discount the historical context of religious dissent at all. Blake would be largely unintelligible without that context. But I think it involves a lot more than "opening a history book" to find historical "facts." I was stating my opinion, not giving an argument. I think the argument first has to make sure that there is a clear understanding of what the big-shot or "official" philosophers were claiming, and then to see how the concepts of the culture of religious dissent could be used to show the internal contradictions in those philosophies. The religious dissenters were concerned narrowly with those churchy issues, Blake wasn't. But since two large contexts are needed before an argument can be made regarding what Blake meant when he talked about Substance and Qualities and Negation and contradiction, I think it's appropriate just to say that I don't think Blake was idiotic enough to have made merely literal use of the vocabulary of religious dissent.

From a previous post:

> I think the historical approach to Blake's diction resolves the paradoxes in favor of Ralph Dumain's suggested interpretation.
>
> This may be your opinion, but how can you possibly argue this on the basis of one quote and no context? I don't think even Ralph, who is an extraordinarily perceptive critic and a very gifted writer, has managed to do anything but list the paradoxes. You refuse even to consider the historical context of religious dissent may have been a factor! The "airhead's" (as opposed to what I might term the "windbags" on the other side of the argument) would have a completely different interpretation of your quote below as having a spiritual connotation, presumably claiming it as an attack on the corruption of worldly religion. I would add the the "reasoning power" (rationalism) is something that Blake clearly rails against, but is a major factor in promoting the radical politics of the era.

Re: Tim's Herring

The Blake List, Volume 1999, Issue 13, February 28, 1999

My recent comment about the political right wing taking art seriously was made in response to the people who are currently trying to separate art from politics, and who would like to limit Blake's political consciousness to religious issues. My remark was topical, but the principle I referred to was broadly historical. Blake appeared to be perfectly conscious of the ways in which not just official censorship, but access to the official exhibitions, and the official promulgation of styles in all the arts, supported the Evil Empire, and oppressed people like him. The tastes of the rich and the ruling classes were met by some painters who collaborated in the destruction of art. After Blake, I don't know of anyone until David Alfaro Siqueiros who so clearly understood the ways in which Money and Empire intervened in art.

From a previous post:

> By the way, the statement about right wing governments and art is a red herring and is very "20th Century centric". Fear of art is only really an issue in societies with some sort of mass media which can use art to spread ideas. Blake lacked anything like this, and in any case many of his target clients were aristocratic patrons! In any case, symbolic and satiric attacks against the establishment were fairly common in the Regency era, and broadly tolerated. More explicit sedition was another thing altogether.

Although Blake used the vocabulary of the religious dissenters, one of his great contributions to culture was his understanding that the bad theologies, and their rationalist definition of matter, had been incorporated into the enlightenment empiricisms and the natural philosophies and sciences. Before Lenin, I don't think there was anyone who perceived the rationalism that was hidden in the crude materialism of the sciences.

I wish that those who would Spiritualize Blake would discuss the term "Nobodaddy," and explain how it fits into a dematerialized world.

To Nobodaddy

Why art thou silent & invisible

The Arts & Sciences are the Destruction of Tyrannies or Bad

Governments Why should A Good Government endeavour to Depress

What is its Chief & only Support

...art and science is fabricated for the purpose of destroying art.

It is the Greatest of Crimes to Depress True Art & Science

The Foundation of Empire is Art & Science...

...& obedient to Noblemens Opinions in Art & Science.

From a previous post:

> I'm not sure of what you mean by your terse statements nor how they address Ralph's questions. Likewise, I'm not sure how you are applying these Blakean Proverbs to your response.
>
> Ralph may often be guilty of being disrespectful, or even vulgar—and someone else's attitudes are simply no excuse for bad writing. But none can dispute that he consistently comes up with some extremely difficult and intriguing questions.

Disrespect and vulgarity aren't necessarily out of place in discussing Blake.

Blake's was the most coherent criticism of the terrible theology hiding within the "Enlightened" philosophies of Hume, Newton, Berkeley, that were in service to empire and commerce.

My point, and Blake's, was that the ruling class knows what it's doing when it controls art and science and philosophy, and art is exactly where political opposition makes its best contribution. My suggestion is that, at present, there isn't much artistic opposition to the New World Order, which is just old-fashioned Empire at its culmination.

I don't know what political application of art might be, application would imply a separation, like a "fund-raising benefit."

I don't know what theoretical statements you refer to. Do you mean about intellectual war? Since Blake tried to develop the idea extensively,

that's where the exactitude could be sought. The references in his works to the philosophical categories that had governmental support in the 18th century make it clear that they are the enemy in his mental war. For me, mental war involves exposing the malevolent and stupid assumptions that impose themselves through the operation of the big sciences, for the benefit of the ruling classes.

Re: Tim's Herring

The Blake List, Volume 1999, Issue 14, March 1, 1999

We might have read the same books, but when I read things by 18th century Tory Gentlemen I try to understand how it was possible to achieve such a uniformly insipid tone of self-righteousness. The academic commentators on art who write that "the true destruction of art" was caused by capitalism are, as far as I have been acquainted with them, trying to imbue themselves with something of the nobility of the earlier ruling classes. Good art was sometimes produced under the catholic church, and that fact is sometimes used to try to separate the "aesthetic" from the "political," though I think it provides more evidence of their linkage. The ideology is heavy in "their motivation was aesthetic, not in any sense political," though it's the ideology that likes to say "I don't have any ideology." Like the academic types who have asserted that "there are no classes in the United States."

From a previous post:

> Blake appeared to be perfectly conscious of the ways in which not just official censorship, but access to the official exhibitions, and the official promulgation of styles in all the arts, supported the Evil Empire, and oppressed people like him.
>
> This sounds rather like uninformed reading from the hymn sheet to me. Anyone who takes the time to look at 18th and early 19th Century political cartoons will realise how little practical censorship existed in the arts. Furthermore, it is a little unfair on institutions like the Royal Academy, who provided free training for artists on the basis of their talent alone. It is true that the hangers at RA exhibitions effectively created trends in artistic taste, but they were taken from amongst the artists themselves, and their motivation was aesthetic, not in any sense political (Blake certainly was represented at the RA from time to time). Incidentally, from the 1850s, the function or arbitor of taste was pretty much ceded to (capitalist) dealers, who in fact still do it, and art has become almost wholly commerce as a result.
>
> In what sense was art destroyed? I'd argue that the plein air naturalism of the early 1800s was in fact a renewal of art, springing from the traditions of Poussin and Gainsborough, and the true destruction of art did not take place until well after Blake's death, when the industrial revolution had created an affluent middle class who wished for decorative

> and sentimentally accesible objects for their front parlours. But then I suspect you read different books than me.

I suppose some people have been impressed by Macauley's "English literature was emancipated forever" by the disappearance of the Licensing Act, but I have never seen any reason to believe that tyrannies take their own laws very seriously. Preventive censorship was replaced by punitive censorship.

In the United States, which hasn't had any Licensing Acts, censorship has been rampant. For example, a college catalog with Blake's Glad Day on the cover, was embargoed by the post office, and couldn't be distributed until language in the text had been deleted.

Do you suggest that Blake was having paranoid delusions when he spoke of the forces that destroy art?

Re: Tim's Herring

The Blake List, Volume 1999, Issue 16, March 1–2, 1999

SINCE I will assume that you have led a remarkably sheltered existence, or else are very young, and so might not be representative of the people in the Blake discussion, I will answer this privately.

I spent many years as a graduate student in several humanities departments of several universities, before I decided that in this country only the sciences tolerate anything like rational dialog. In English, philosophy, linguistics, art history, uniformly the professors mouthed that moronic party line, "there are no classes in the United States," and my fellow students were if anything even more strident. Later, I had friends in departments of sociology who used elaborate rationalizations to justify the same assertions. The sociological literature is full of their crap; the reaction to G. William Domhoff's work was essentially one of hysterical denial. One of the variations on the theme extends into psychology and biology, arguing that since everyone has the same opportunity in this classless society, social differences are really just a natural expression of innate inferiority and superiority. For my entertainment, I would occasionally insert into my seminar papers things that could be taken as defense of such elitism, and these were always the occasion for glowing approval by the asshole professors.

The cover of Emanations from Blake College was enclosed as first class mail, and it was therefore inappropriate for the postmaster to open it, but the image, faintly detected through the envelope, was apparently an excuse to examine the contents of the book. The text that was forbidden was by Gregory Corso, a dialog with Alan Ginsberg. The postmaster, a Republican, was nevertheless a kind man, who returned the 300 copies to me for correction, rather than destroying them. I mentioned that, not because it was unusual as an illegal act of censorship, but because the Blake engraving was the trigger. Two of my uncles were postmasters, so I heard inside stories of postal service behavior, but the periodicals of the 20th century give many more famous examples.

From a previous post:

> I do have, however, two questions prompted by some nearly incomprehensible parts of Mr. Peat's recent post—first: please cite some "academic types" who claim that the USA is a classless society???? I have

read a good deal of commentary on American history and culture, and the notion that it is a common or even an occasional *academic* point of view that US is a classless society comes as a considerable surprise to me. On the contrary, it is usually *academics* who cry in the wilderness against the "common wisdom" that the USA is "classless."

Second: please clarify the event cited with reference to the college catalogue with "Glad Day" on the cover????? The Postal Service "embargoed" it until "the language of the text inside" was altered? This is truly incomprehensible. Why would the presence of a picture on the cover require the alteration of the text inside? How would that solve any problem? Presumably, the "embargo," assuming it ever occurred and is not an example of a foaf tale, would have been caused by the exposed male genitalia on the cover, not by text inside. Very odd narrative, but possible as a form of urban belief legend.

Tim's Aristocrats

The Blake List, Volume 1999, Issue 16, March 1–2, 1999

WRITING and other mental works provide windows into the times and situations of their creators, and I consider Blake to be the best window into the 18th century. If preserving the arts and sciences, the accumulated wisdom of the ages, is very important, then I think it is useful to assume that Blake wasn't in a delusional state when he ranted or grumbled about the class that destroys art and knowledge, and to give serious consideration to what he meant.

"…most informed observers"—is that still an accepted rhetorical device in academic discussion?

Altruistic English aristocratic patrons of the 18th century, I recognize the concept, but to accept it as an important fact seems to be giving too much weight to their own testimony and judgment.

In our century, the commercial forces that you suggested were harmful to art, have more resources than ever before to manipulate tastes. Publishing, academic endowments and direct manipulation of state institutions are used to validate their preferred interpretive frameworks, and ultimately the judgments that are made about history, literature, science, and painting, have to be made in this extremely polluted atmosphere. That's why I think it's important to see Blake's remarks on the destruction of art in a sense more general, and less subjective, than just the issue of blurring painted forms.

From a previous post:

> Do you suggest that Blake was having paranoid delusions when he spoke of the forces that destroy art?
>
> This is certainly a possibility.
>
> However, what Blake meant by the "destruction of art" was the blurring or removal of the "bounding line", a tendency to employ chiaroscuro, admiration for the Flemish masters, and the movement towards naturalistic realism in landscape (all of which, incidentally, were characteristics of the work of John Linnell at the time he and Blake were close friends, so clearly Blake did not feel all that strongly about it). This is not "destruction" in anything other than a highly personal and subjective sense.
>
> In actual fact, I would venture to suggest that most informed observers would say that the first twenty or thirty years of the last century was one of the better periods for English art. Where things did drift into

crass and sickly sentimentality and "production line" art was when the dealers got involved and the whole exercise became commercial, leading to the great art boom in the late 1800s. Furthermore, dealers put great pressure on the hangers at the RA and other exhibitions to favour artists they represented.

On the other hand, aristocratic patrons viewed their contribution to art as somewhat altruistic, and tended not to interfere with the artist's work. The hangers at exhibitions were taken from among the artists themselves and were more or less in tune with the direction their fellows wished to go, within certain parameters of conventional taste (which are inevitable). Although not perfect, this was a fundamentally much more healthy situation for the development of art than the dealer led commercialization.

Tim's Definition

The Blake List, Volume 1999, Issue 13, February 28, 1999

I think Tim's argument is doing an injustice to history, as much as to Blake. If Blake used the vocabulary of 18th century songs of religious dissent in attacking State and Class oppression, and therefore was spiritual rather than political, then the people who sang christian hymns while marching in the streets of the United States were primarily interested in religion, and the communists among them were for the moment no longer political revolutionists. That's no way to argue.

From a previous post:

> So the quote above is not political, except in the sense that opposition to a political entity is a political act,

To me, this is an astounding statement. Does it suggest that the writings of Marx and Engels in themselves weren't unqualifiedly political?

From a previous post:

> But in view of the fact he did nothing tangible to promote or implement his views, one has to say that if he was a political writer, he failed.

Don't most political writers fail? What's the point? Can you comfortably and historically assert that Blake did "nothing tangible to implement his views"? Are political pamphlets political only if they lead to revolutions?

From a previous post:

> I can only assume that the misinterpretation of a quote with a clear and blindingly obvious religious dissenting content is based on ignorance of the history of religious dissent, His adoption in our times is not because he has anything particularly new to say, but because he had the good fortune to have written a few things which had resonance with post war student politics, he appears to advocate free love

Why is your interpretation of a certain passage blindingly obvious, while you frame his advocacy of free love as an appearance? Robinson thought Blake's advocacy was embarrassingly blatant.

From a previous post:

> In any case, I think the answers to Ralph's questions are simple. He raises paradoxes based on his assumption that Blake used symbolic constructs to frame his political ideology and in fact had no spiritual objectives. The fact of the matter is that Blake actually believed what he said to have literal truth. If you apply this idea to what he said, even if you don't agree with him, the paradoxes vanish.

I think the historical approach to Blake's diction resolves the paradoxes in favor of Ralph Dumain's suggested interpretation.

Pharmaceutical Compositions Containing Dehydroepiandrosterone and Other Anesthetic Steroids in the Treatment of Arthritis and Other Joint Disabilities

United States Patent, December, 1986

Background of the Invention

This invention is concerned with compositions and methods of treating rheumatoid arthritis, osteoarthritis, and arthritis associated with psoriasis and with lupus and other auto-immune diseases, and also for treating non-specific joint pain associated with stress or incidental to another ailment, using dehydroepiandrosterone (DHEA) and/or other anesthetic steroids dissolved in an oily vehicle, and preferably administered topically or orally.

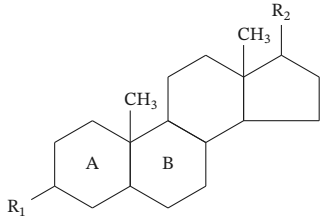
The extensive use of cortisone and related anti-inflammatory steroids in treating arthritis has been limited by the knowledge of several side effects, including calcium loss and osteoporosis, immune suppression, and atrophy of various tissues, including the adrenal glands. Nonsteroidal anti-inflammatory agents have been used with some success to avoid the glucocorticoids' side effects, but generally are ineffective in preventing the advance of the disease process. Other agents have been used or proposed which retard the advance of the disease, possibly by inhibiting mitosis, but they generally have toxic side effects.

It would be desirable to use in treatment substances which are normally present in the body at high levels, since these normal substances, especially when used in physiological quantities, rarely have harmful side effects.

The improvement which sometimes occurs during pregnancy in women suffering from arthritis has led to the experimental use of some of the hormones of pregnancy in treating arthritis, but the female sex hormones would obviously produce side effects when used in large doses in males.

Some steroidal substances, however, lack conventional hormonal activity and are normally present in significant amounts in both males and females. A number of such steroids, e.g. dehydroepiandrosterone, are present

in elevated quantities during pregnancy. Such steroids have received little attention since they have been considered to be only chemical intermediates or end products destined for nothing more important than to be excreted. It was therefore surprising to find that a number of these substances are useful in the treatment of arthritis and related diseases.



It is an object of this invention to provide an anti-inflammatory pharmaceutical preparation useful for the treatment of arthritis and lacking undesirable hormonal side effects. It is a further object of this invention to provide such a pharmaceutical preparation in a form suitable for administration locally to the affected joints without requiring injection.

Summary of the Invention

The present invention is concerned with compositions and methods of treating rheumatoid arthritis, osteo-arthritis, and arthritis associated with psoriasis and with lupus and other auto-immune diseases, and also for treating non-specific joint pain associated with stress or incidental to another ailment, using dehydroepiandrosterone and/or other anesthetic steroids dissolved in an oily vehicle, and preferably administered topically or orally.

Detailed Description of the Preferred Embodiments

Arthritis, including rheumatoid arthritis, osteo-arthritis and arthritis associated with psoriasis and with lupus, as well as other auto-immune diseases, and non-specific joint pain associated with stress or incidental to another ailment, may be successfully treated by administering to a subject in need of such treatment, including a human patient, an effective amount of an anesthetic steroid, preferably a natural anesthetic steroid having 19 or 21 carbons, more preferably selected from compounds of the formula:

wherein R_1 is O or OH and R_2 is O, OH, or $COCH_3$; and which may contain one double bond in ring A and/or ring B.

Examples of such compounds are dehydroepiandrosterone (DHEA), iso-androsterone, etiocholanolone, progesterone, and pregnenolone.

Combinations of such steroids may be used. When the patient being treated is male, combinations containing testosterone are preferably used.

Compounds considered to be equivalent to the foregoing and also falling within the scope of this invention are steroids of the above-depicted structure having H, methyl, fluorine, or chlorine substituents, as well as easily hydrolyzable esters of all the foregoing.

Suitable pharmaceutical compositions for use according to this invention comprise at least one of the above-described compounds, together with suitable pharmaceutical carriers and/or diluents, preferably the carriers specified in the preferred embodiments described below. In such pharmaceutical compositions, the proportion of therapeutically active to carrier substance can vary between about 1 % to 99 % by weight. The compositions can be prepared in various pharmaceutical forms, such as granules, tablets, pills, suppositories, capsules, suspensions, salves, lotions, and the like. Pharmaceutical organic or inorganic carriers and/or diluents suitable for oral and topical use can be used to make up compositions containing the therapeutically active compounds. Diluents known to the art include vegetable and animal oils and fats. Stabilizing agents, wetting and emulsifying agents, salts for varying the osmotic pressure or buffers for securing an adequate pH value, and skin penetration enhancers can be used as auxiliary agents. The compositions may further contain other therapeutically active compounds, e.g. selected from the group of drugs commonly used in the treatment of arthritis.

For oral use, the pharmaceutical composition of the invention appropriately contains from about 10 % to 100 % by weight of the active material. For topical use, the composition appropriately contains from about 1 % to 15 % by weight of the active material.

Generally for oral use it is preferred that the active ingredients in dry form be mixed with tocopherol to form a paste for capsuling. For topical use, solubilization in tocopherol and olive oil is preferred.

A preferred composition for oral use comprises about 10 mg of the active material, preferably DHEA, about 50 mg pregnenolone, about 5 mg progesterone in 1200 mg tocopherol.

A preferred composition for topical use comprises 5 % of the active material, preferably DHEA, 80 % mixed tocopherols, and optimally up to 10 % olive oil and up to 3 % progesterone. Testosterone up to about 0.5 % may also be added.

The dosage required may vary from about 10 mg to 200 mg active material orally, or 400 mg to 1000 mg active material topically, and may be repeated twice per day.

Generally, for oral administration, a single dosage of about 10 mg to 50 mg of therapeutically active compound in an appropriate carrier is effective. For topical use, a preparation containing about 8 % of therapeutically active compound should be spread in a single application on the skin over the painful area in an amount of between about 0.05 mL to 0.2 mL per square inch of skin. The preparation should be thoroughly rubbed in, and the area covered to avoid rubbing away of the compound before absorption. Warmth may be applied locally to speed absorption.

The invention will be further described in the following examples which are not to be construed as limiting the invention.

Example 1

Combined were 100 mg of micropulverized pregnenolone with 100 mg of 10 % DHEA in tocopherol to form a paste which was capsuled for oral use.

Example 2

For oral use, 100 mg of micropulverized pregnenolone was combined with 50 mg of 10 % DHEA and 50 mg of 10 % progesterone to form a paste which was capsuled.

Example 3

For topical use, a mixture containing 72 % tocopherol, 20 % olive oil, 5 % DHEA, 2.85 % progesterone, and 0.15 % testosterone was prepared by stirring the steroids into the tocopherol until dissolved, then adding the olive oil.

Example 4

The following case histories illustrate the effectiveness of the compositions of this invention in treating arthritis and joint pain:

Case 1. A 78 year old man. He was considered to have mild osteo-arthritis, mainly in his knees. For a few years he had found it increasingly difficult and painful to rise after sitting and to walk. He coated each knee and the immediately adjoining area with a solution containing 2.5 % dehydroepiandrosterone and 2.5 % progesterone in a solvent consisting of equal amounts of mixed tocopherols and olive oil, and remained sitting for two hours. He rose easily, walked without pain, and his knees

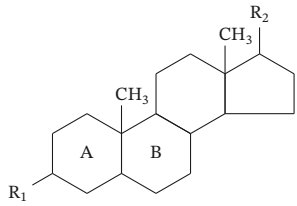
remained comfortable without another application of the solution. A week later he applied a 3% solution of dehydroepiandrosterone to his hands, and reported elimination of pain and increased flexibility within an hour. He has remained free of symptoms for eight months with continued treatment.

Case 2. A 72 year old woman. She was considered to have mild rheumatoid arthritis which was degenerating into osteo-arthritis, with her fingers being the most seriously affected joints. A 3% solution of dehydroepiandrosterone in olive oil was applied to one index finger, and a 10% solution of progesterone in mixed tocopherols was applied to the other index finger. All of her fingers had been rigid for over a year, with the result that she was extremely disabled. Forty minutes after the dehydroepiandrosterone solution had been applied, the finger treated with the composition containing dehydroepiandrosterone could be bent enough to touch the base of her thumb, without significant pain, but none of her other fingers showed any improvement. Several days later, the dehydroepiandrosterone solution was applied to all of her fingers, with similar good results. After about 6 months, stiffness and pain returned in spite of use of DHEA, and progesterone added to the treatment caused continued improvement.

Case 3. A 60 year old woman with a long history of rheumatoid arthritis and with serious degeneration of many joints. She had undergone surgery several times, for implantation of two artificial joints and for repair of joint cartilage. She walked as little as possible, and experienced pain, inflammation and fatigue from excessive walking. She applied a solution containing 7% dehydroepiandrosterone and 3% progesterone in solvent consisting of tocopherol, 90%, and olive oil, 10%. She applied the solution several times one afternoon and the next morning to all affected joints, including hands, wrists, elbows, knees, and ankles. She experienced what she said was complete relief, and spent the next two days walking around the town sightseeing, without any of the after-effects she had previously experienced from walking.

Case 4. A 61 year old man with mild, unclassified arthritis of the thumb and fingers of his right hand, which prevented him from playing golf, but was otherwise not seriously disabling. A solution essentially identical to that used in Case 3 was rubbed into the painful joints. In less than fifteen minutes he said that all the pain was gone, even with pressure and movement.

Case 5. A 62 year old man. His knees had been stiff, painful, and inflamed for over two years, following an accidental fall onto his knees. Arthroscopic examination revealed damaged cartilage in his right knee, and surgery was recommended to restore function. The patient refused surgery, even though he walked with difficulty and had to use his left leg, which was also affected, to lift himself slowly up steps. He said he had not slept well since he had developed the arthritis, because the pain woke him repeatedly during the night, and only the use of an analgesic would allow him to go back to sleep. He coated his knees and the skin above and below the knees to a distance of about four inches from the knee, with a total of 20 mL of a solution essentially identical to that used in Case 3. Within 30 min he appeared to be able to walk more normally, and about 45 min after applying the solution he remarked that he believed he was able to walk more easily. He repeated the application that night before going to sleep. Around 10 o'clock the next morning he returned and laughingly demonstrated his knees by running up the stairs, and said that he had been able to sleep through the night for the first time in years, and had not taken his usual analgesic. Topical treatment was discontinued after a few days, and he remained free of symptoms while taking 60 mg of pregnenolone orally, daily.



Case 6. A 61 year old woman. Painful and stiff joints in her hands had interfered with her work as a musician, and had made it impossible to sleep through the night, since the pain woke her two or three times during the night. A solution essentially identical to that used in Case 3 was applied to the painful joints early in the evening, and a few hours later she was able to go to sleep without taking analgesic and slept through the night. She occasionally uses the same solution preventively, and has not had a recurrence of the joint pain or stiffness.

Claims

What is claimed is:

1. A method for treating arthritis and joint pain and disability, comprising administering to a patient in need of such treatment a pharmacologically effective dose of dehydroepiandrosterone.

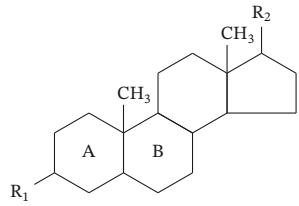
2. A method for treating arthritis, comprising administering to a patient in need of such treatment a pharmacologically effective dose of at least one compound selected from the group of the anesthetic class of naturally occurring steroids of the formula:

wherein R_1 is O or OH and R_2 is O, OH, or $COCH_3$; and which may contain one double bond in ring A and/or ring B.

3. The method of claim 2 in which said steroid is selected from the group consisting of dehydroepiandrosterone, iso-androsterone, etiocholanolone, pregnenolone, and progesterone.

4. The method of claim 2 wherein the compound is administered orally.

5. The method of claim 2 wherein the compound is administered topically.



6. The method of claim 2, wherein the arthritis to be treated is osteo-arthritis.

7. The method of claim 2, wherein the arthritis to be treated is rheumatoid arthritis.

8. The method of claim 2, wherein the arthritis to be treated is arthritis associated with auto-immune disease.

9. The method of claim 2, wherein the condition to be treated comprises non-specific joint pain or joint disability resulting from stress.

10. A pharmaceutical composition useful for the treatment of arthritis comprising an effective amount of at least one compound selected from the group consisting of the formula:

wherein R_1 is O or OH and R_2 is O, or OH; and which may contain one double bond in ring A and/or ring B and tocopherol, in a suitable pharmaceutical carrier.

11. The composition of claim 10 in which said steroid is selected from the group consisting of dehydroepiandrosterone, iso-androsterone, and etiocholanolone, in a suitable pharmaceutical carrier.

12. The composition of claim 11 comprising an effective amount of dehydroepiandrosterone and tocopherol.

13. The composition of claim 11 also comprising progesterone.

14. The composition of claim 11 also comprising testosterone.

15. The composition of claim 11 also comprising olive oil.

Treatment of Progesterone Deficiency and Related Conditions With a Stable Composition of Progesterone and Tocopherols

United States Patent, March, 1984

The present invention relates to the composition of a biologically compatible high concentration solution of progesterone in tocopherol, with or without modifying substances, which can be used transdermally, orally, and in suppository and pessary form, for the correction of progesterone deficiency states and other diseases.

Progesterone deficiency can be defined in relation to a norm, and also in relative terms, taking into account the absolute level of progesterone in the tissues and the presence and levels of antagonists to its actions, including estrogens, prolactin, and androgenic steroids, and it can also be defined in the empirical sense, in which symptoms abate when progesterone is administered.

Physicians have long sought an oral and/or transdermal form of progesterone which is stable in high concentration and which is assimilated easily by the body, for use when injectable forms of progesterone are not tolerated. A nontoxic and low-allergenic form is of special value for use in allergic patients, and for all users the absence of a toxic solvent is of obvious value.

Many physicians have used progesterone dissolved in ethanol, but ethanol has a higher mutual solubility with water than with progesterone, causing the bulk of the progesterone to be crystallized out of solution as the alcohol solvent mixes with biological fluids. That composition is ineffective because it fails to deliver progesterone in practical quantities and usable form. Other compositions containing solvents such as benzyl benzoate, benzoyl alcohol or phenol are limited in their applicability because of their toxicity, irritating properties, or allergenicity. Since allergies are common in the condition of progesterone deficiency, it follows that the effectiveness of compositions containing allergenic solvents is limited.

Progesterone has been used medically to treat pregnancy complications, menstrual abnormalities, menopausal difficulties, sev-

eral types of malignant and non-malignant tumors, neurological and psychological symptoms, and many other specific problems. The composition described in this patent can be used effectively for all of the purposes for which progesterone in its older compositions is effective. In addition, the composition described in this patent is useful for several new purposes, including treatment of psoriasis, eczema, senile skin changes including warts, superficial burns, allergies, abnormal hair growth resulting from androgen excess, intestinal inflammation and bowel spasms, migraine, and for promoting maturation of thymus-derived lymphocytes, and as a contraceptive.

It is an object of the present invention to provide a composition and method for the treatment of progesterone deficiency conditions.

It is another object of the present invention to provide such a composition and method which overcome the shortcomings of the prior art.

It is another object of the present invention to provide a composition which does not decompose into solvent and crystallized solute, progesterone, under any presently known conditions of storage or use.

It is another object of the present invention to provide such a composition which is non-toxic and which may be used frequently over long periods without adversely affecting the tissues which it contacts.

It is a further object of the present invention to provide such a composition which is economical and easily used for the prevention and treatment of progesterone deficiency conditions and other diseases.

Still further objects and the entire scope of applicability of the present invention will become apparent from the detailed description and specific examples, but it should be understood that the examples, while indicating preferred embodiments of the invention, are given only for illustration, since changes within the spirit and scope of the invention will become apparent to those skilled in the art from this description.

It has been found that the above objects may be attained by a composition which contains as essential ingredients progesterone and tocopherol. As will be hereinafter explained more fully, the composition may also contain additives for various purposes. The composition may be administered by spreading on the skin, by holding in contact with mucous mem-

branes, or by ingesting, and can be used as frequently as needed.

Suitable forms of tocopherol include d-alpha tocopherol, and mixed tocopherols of the dextro-rotatory form.

Suitable additives include coconut oil, palm kernel oil, jojoba oil, and olive oil, used in concentrations up to about 15 % to lower the viscosity of the solution and to thus speed absorption; ascorbyl palmitate and/or glyceryl monophosphate in concentrations sufficient to emulsify the composition with water; biological or organic gels including aloe gel and extracts from marine algae to thicken the consistency and to stabilize the emulsion; and ethanol, in a concentration of up to about 7 % by volume, to modify consistency and to increase absorption of progesterone.

The composition is prepared by mixing the ingredients to obtain a homogeneous product. Stirring at room temperature is adequate, but may require several days to reach complete homogeneity. An oxygen-free atmosphere is preferred but not essential. If higher temperatures are used for faster mixing, an oxygen-free atmosphere becomes more important to prevent oxidation of the materials.

Progesterone and tocopherol can be mixed in the proportions of from 1 % to 25 % progesterone by weight, to about 75 % to 99 % of tocopherol, with a preferred concentration for most uses of from about 10 % to 20 % progesterone to about 80 % to 90 % tocopherol.

This invention is further described in the following specific examples, which are to be considered only as illustrative of preferred embodiments of the present invention.

Example 1

10 kg of progesterone is added to 90 kg of mixed tocopherols of the dextro-rotatory form, and stirred at a temperature of 45 °C until homogeneous. 35 kg of glyceryl-monostearate is added to the composition and stirred at 45 °C until a homogeneous mixture is produced. This oil phase is then homogenized at 45 °C with a water phase composed of 200 kg of water mixed homogeneously with 5 kg of dry aloe gel, and 1 kg of sorbic acid as a preservative.

The resulting emulsion is then applied to the skin in treating systemic progesterone deficiency, and for treating local skin conditions including psoriasis, or applied to a vaginal diaphragm or pessary or inserted vaginally with an appropriate applicator, for use as a contraceptive or for treating systemic progesterone deficiency.

Example 2

20 kg of progesterone is added to 80 kg of mixed tocopherols, and stirred at a temperature of 40 °C until homogeneous.

The resulting composition is applied to a pessary for use as a contraceptive, or as a local treatment for dysplasia of the uterine cervix, or is administered orally for treatment of a systemic progesterone deficiency. No preservative is needed in this composition.

Example 3

10 kg of progesterone is added to 90 kg of d-alpha tocopherol and stirred at a temperature of 30 °C until homogeneous.

The resulting composition is then encapsulated and administered orally for treatment of systemic progesterone deficiency.

Claims

What is claimed is:

1. A composition consisting essentially of progesterone solubilized in tocopherol.

2. A pharmaceutical composition suitable for administering progesterone to a patient in need thereof, comprising a pharmaceutically effective amount of progesterone solubilized in tocopherol.

3. The composition of claim 2 wherein progesterone is present at a concentration of from about 1 % to 25 % by weight.

4. The composition of claim 2 also containing an emulsifier, water and a preservative.

5. A method for administering progesterone to a patient in need thereof comprising administering to said patient by means other than intravenous injection, a pharmaceutically effective mixture of progesterone solubilized in tocopherol.

6. The method of claim 5 which comprises the oral administration of said mixture.

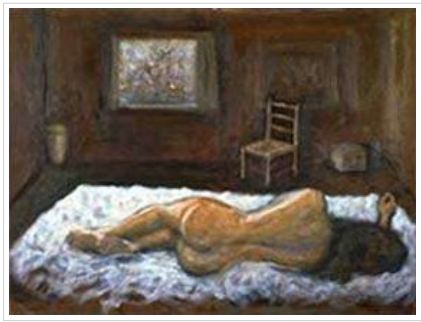
7. The method of claim 5 which comprises the topical administration of said mixture.

8. The method of claim 5 which comprises placing said mixture in contact with the mucous membranes of the patient.

9. The method of contraception in which a pharmaceutically effective amount of progesterone solubilized in tocopherol is applied to the vaginal membranes and the uterine cervix by means of a vaginal diaphragm, a pessary, or other means of vaginal application in which the composition is retained within the vagina for about four hours or more after each application.

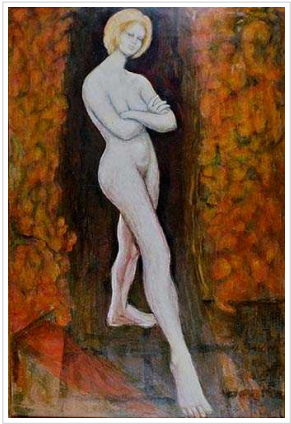
10. A method for making a pharmaceutically effective composition for the administration of progesterone to a patient in need thereof comprising solubilizing progesterone in tocopherol.

Paintings



> "I think of myself primarily as a painter who doesn't have any customers."
>
> — Ray Peat

PAINTING and science have been closely associated historically, because both used to involve close, intense examination of their subject, generalization based on experience, and imaginative consideration of the possibilities. That has changed but not because of any intrinsic change in knowledge.



Knowledge always changes through time, but vested interests try to permit only those changes that are good for them. Authoritarian education derives its authority from political and economic power, and generally not from the quality of the knowledge it inculcates. As education became more important economically in the twentieth century, it became more specialized, in the sense that each teacher devoted his full time to an increasingly narrow topic. In this state, the specialist loses his authority when he ventures to evaluate the big picture.

In the 19th century, biologists were usually competent painters, but as specialization took over at the beginning of the 20th century, both science and painting became "abstract." Mathematics came to be called the language of science, and a science was considered to be more scientific when it was more mathematical. The mathematical habit of mind inclines biologists to see organisms as disembodied information, ultimately as the information contained in the genetic code. Change (they are likely to say) is random, "chaotic," ultimately unknowable. There is no place in this system for a radical critic of the purpose and direction of the system.

If physicists and biologists learn to see the world in a lively way by exercising the power to paint, they will learn to prevent the atrophy of their critical powers.
